(February 2007)

This article considers recent advances in the investigation of the thermal and magnetic properties of integrable spin ladder models and their applicability to the physics of strong coupling ladder compounds. For this class of compounds the rung coupling $J_{\perp}$ is much stronger than the coupling $J_{\parallel}$ along the ladder legs. The ground state properties of the integrable two-leg spin- $\frac{1}{2}$ and the mixed spin- $(\frac{1}{2}, 1)$ ladder models at zero temperature are analysed by means of the Thermodynamic Bethe Ansatz (TBA). Solving the TBA equations yields exact results for the critical fields and critical behaviour. The thermal and magnetic properties of the models are discussed in terms of the recently introduced High Temperature Expansion (HTE) method, which is reviewed in detail. In the strong coupling region the integrable spin- $\frac{1}{2}$ ladder model exhibits three quantum phases: (i) a gapped phase in the regime $H < H_{c1} = J_{\perp} - 4J_{\parallel}$, (ii) a fully polarized phase for $H > H_{c2} = J_{\perp} + 4J_{\parallel}$, and (iii) a Luttinger liquid magnetic phase in the regime $H_{c1} < H < H_{c2}$. The critical behaviour in the vicinity of the critical points H_{c1} and H_{c2} is of Pokrovsky-Talapov type. The temperature-dependent thermal and magnetic properties are directly evaluated from the exact free energy expression and compared to known experimental results for the strong coupling ladder compounds $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$, $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$, $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$, BIP-BNO and $[\text{Cu}_2(\text{C}_2\text{O}_2)(\text{C}_{10}\text{H}_8\text{N}_2)_2](\text{NO}_3)_2$. Similar analysis of the mixed spin- $(\frac{1}{2}, 1)$ ladder model reveals a rich phase diagram, with a $\frac{1}{3}$ and a full saturation magnetization plateau within the strong antiferromagnetic rung coupling regime. For weak rung coupling, the fractional magnetization plateau is diminished and a new quantum phase

¶ zengo_tsuboi@pref.okayama.jp

transition occurs. The phase diagram can be directly deduced from the magnetization curve obtained from the exact result derived from the TBA and HTE. The results are applied to the mixed ferromagnetic ladder compound PNNBNO. The thermodynamics of the spin-orbital model with different single-ion anisotropies is also investigated. For this model single-ion anisotropy can trigger different quantum phase transitions within the spin and orbital degrees of freedom, with magnetization plateaux arising from different spin and orbit Landé g -factors.

1 Introduction

The subject of integrable or exactly solved models in statistical mechanics has inspired a number of profound developments in both physics and mathematics. There are several key solvable models in low dimensions, the analysis of which has developed to an extraordinary level of mathematical sophistication. This article is concerned with the calculation of physical properties of the integrable quantum spin ladders and their applicability to experimental ladder compounds. By integrable it is meant that the ladder models are exactly solvable in the Yang-Baxter sense [1, 2, 3], with infinitely many conserved quantities and an underlying Bethe Ansatz solution. Most importantly, this entails access to the thermodynamic properties [4, 5]. In this way the theory of integrable models, which has developed for over 75 years since Bethe's [6, 7] pioneering solution of the $su(2)$ Heisenberg chain, has recently been applied [8] to make direct contact with experiments on spin ladder compounds. The integrable ladder models, for example, the two-leg spin- $\frac{1}{2}$ ladder and the mixed spin- $(\frac{1}{2}, 1)$ ladder, are variants of the $su(4)$ and $su(6)$ models based on the general family of integrable $su(N)$ permutator models [1, 2, 9, 10, 11]. Their two-dimensional classical lattice model counterparts are the N -state A_{N-1} vertex models [12, 13], which are special cases of the Perk-Schultz model [14].

1.1 Physical motivation

Over the last few decades there has been considerable theoretical and experimental interest in low-dimensional quantum spin systems. One focus of attention is the spin liquid behaviour. It is well established that the critical behaviour of the one-dimensional Heisenberg spin chain in the absence of frustration depends on the spin magnitude S , i.e., on whether $2S$ is an even or odd integer. In one dimension the quantum fluctuations are so strong that the long range Néel order no longer survives. For $2S$ odd the spin chain has low-lying gapless excitations with a power law spin-spin correlation [15]. On the other hand, for $2S$ even the spin-spin correlations decay exponentially due to the Haldane gap [16, 17]. In two-dimensional quantum spin systems the quantum fluctuations compete with the thermal fluctuations for domination of the critical behaviour at low temperatures. Here long range Néel order is

possibly stable against quantum fluctuations.

Spin ladder systems, which intermediate between one-dimensional and two-dimensional spin systems, exhibit rich and novel phase transitions and a diverse range of quantum magnetic effects at low temperatures [18, 19, 20, 21]. The long range Néel order phase emerges when the interaction between the adjacent two-leg ladders is greater than some critical value [22]. However, if the two-leg ladder structures are well isolated from each other, the intra- and inter-chain interactions induce rich spin liquid phases, such as gapped dimerised and gapless phases. The existence of a spin gap, magnetization plateaux, quantum critical points and superconductivity under hole doping are examples of key physical properties observed in the ladder compounds. The physics of the spin ladder systems reveals a significant pairing effect, namely the Heisenberg spin ladders have an energy gap in the spin excitation spectrum if the number of ladder legs is even, whereas there is no gap for an odd number of legs [18, 19, 20]. This similarity with the above mentioned Haldane conjecture for spin- S chains arises from the fact that the ladder model can be mapped onto a one-dimensional counterpart with on-site anisotropy or next-nearest-neighbour interaction, at least in the strong coupling limit [23, 24]. In addition, the ladder systems have been argued to provide simple models relevant to the mechanism for high temperature superconductivity in layered cuprate superconductors [20]. The challenge for theorists is to calculate and to predict the properties of the ladder systems.

1.2 Experiments and theories for ladders

The experimental study of ladder systems was initiated from the observation that the compound $(\text{VO})_2\text{P}_2\text{O}_7$ has a singlet ground state with an energy gap in the spectrum of spin excitations [25]. Subsequently, the theoretical study of ladder systems began when the hole-doped two-leg t - J ladder was found to exhibit a finite spin gap [26]. In this model, at each site the ions are either in a spin- $\frac{1}{2}$ Cu^{2+} state or a Cu^{3+} hole state. Hole ions are bound along rungs so that the spin- $\frac{1}{2}$ Cu^{2+} ions form rung singlets. This configuration leads to superconducting pairing correlations [26, 20]. In this context, there have been many theoretical papers focussing on hole-doped ladders, see Refs. [20, 27]. Experimental superconducting ladder compounds, e.g., $(\text{La}, \text{Sr}, \text{Ca})_{14}\text{Cu}_{24}\text{O}_{41}$ [28, 29] and other doped ladder compounds, e.g., $\text{LaCuO}_{2.5}$ with Sr doping [30, 27], provide experimental evidence of superconductivity. In Cu-based ladders, the hole doping provides a “d-wave” channel for a superconducting phase [26, 20]. In this article we focus on undoped or pure spin ladder materials for comparisons with the theoretical results.

The Heisenberg antiferromagnetic spin- $\frac{1}{2}$ ladder model was first proposed in Ref. [18]. It is known that the Heisenberg coupling $J_{\perp}$ along the rungs can

open a gapped phase for arbitrary coupling strength. If $J_{\perp} = 0$, the ladder decouples into two non-interacting spin- $\frac{1}{2}$ Heisenberg chains, with no gap to spin excitations [15]. The decoupled chains are in critical states exhibiting no long range order. In the presence of weak interchain interactions (small $J_{\perp}$), the lowest spin excitation can be separated from the ground state by an energy gap of magnitude $\Delta \approx J_{\perp}/2$ [20, 27, 31, 32, 33]. Essentially, the weakly coupled ladder models may exhibit antiferromagnetic long-range order at finite temperatures. For example, the trellis layer structure of the $\text{Sr}(\text{Cu}_{1-x}\text{Zn}_x)_2\text{O}_3$ lattice with nonmagnetic isoelectronic Zn^{+2} doping [34, 35] was found to induce long-range Néel order. It was verified experimentally that the undoped two-leg ladder compound SrCu_2O_3 exhibits a spin gap, but the three-leg ladder compound $\text{Sr}_2\text{Cu}_3\text{O}_5$ does not [36, 37, 38]. In the strong coupling limit, the ground state of the two-leg ladder compound is dimerised along the rungs. The intrachain interaction between neighbouring magnetic moments is quenched by the formation of a rung singlet state. In order to create a spin excitation the rung singlet must be replaced by a rung triplet. Breaking the rung singlet causes an energy gap $\Delta \approx J_{\perp} - J_{\parallel}$ which separates the lowest excited state from the dimerised ground state [20, 22, 39]. Here $J_{\parallel}$ is the (intrachain) coupling along the ladder legs. The number of legs significantly affects the magnitude of the spin gap. For an even number of spin- $\frac{1}{2}$ ladder legs the gap decreases as the number of legs grows [36, 37], as one would expect as the ladder becomes more like a two-dimensional antiferromagnet. The ground state is a spin singlet with zero total spin. For an odd number of legs with strong rung coupling, the ground state is a magnetic degenerate state with total spin $S = \frac{1}{2}$, with algebraically decaying spin-spin correlations and no gap to spin excitations. The qualitatively different behaviour between even- and odd-leg spin ladders has been discussed at length [32, 40, 41, 20].

Of particular interest are the strongly coupled ladders as their energy gaps are experimentally accessible. Many organic spin ladders with strong rung coupling have been synthesised. In particular, $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$ [42] $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$ [43, 44, 45, 46] and $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$ [47] have a well isolated ladder structure. The ladder structure for the compound $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$ is shown in figure 1. This compound is made up of effective two-leg spin- $\frac{1}{2}$ ladders with strong antiferromagnetic rung interaction through superexchange between adjacent molecular units. The interchain coupling between Cu-Cu ions is parametrized by the rung coupling $J_{\perp}$. The dimeric units along each rung are weakly linked to the nearest neighbour ones through hydrogen bonds along the [101] chain direction. The exchange between two neighbouring rungs is much weaker than the intradimer path. This intrachain coupling is denoted by the parameter $J_{\parallel}$. It is believed that the family of compounds KCuCl_3 , TiCuCl_3 , NH_4CuCl_3 and KCuBr_3 also exhibit such double-spin-chain structure [48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62]. These double-chain

Figure 1. The schematic structure of the two-leg spin ladder compound $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$. The Cu-Cu binuclear units along the chain direction [101] form the intrachain interaction. The superexchange paths between two Cu ions along each rung form the interchain interaction. Reproduced from Ref. [46].

compounds have been studied extensively from both the theoretical and experimental points of view.

The Heisenberg ladder model, with antiferromagnetic spin-spin interactions along the legs and rungs, describes these compounds rather well. The strong coupling compounds have a singlet ground state for magnetic fields less than a critical value H_{c1} . The theoretical prediction for the energy gap is $\Delta \approx J_{\perp} - J_{\parallel}$ [63, 64, 20], which is in excellent agreement with the experimental results, obtained from Nuclear Magnetic Resonance measurements [44], along with high field magnetic properties [59, 42, 65, 50]. In addition, the susceptibility $\chi \propto e^{-\Delta/T}/\sqrt{T}$ with energy gap Δ obtained from the quantum transfer matrix method [66] generally provides a good fit for the strongly coupled two-leg ladders. For magnetic field $H > H_{c1}$ the triplet rung state enters into the ground state, with a gapless Luttinger phase in the regime $H_{c1} < H < H_{c2}$. The critical field H_{c2} indicates a quantum phase transition separating the Luttinger liquid magnetic phase from a fully polarized state. It was suggested [67] that the gapless phase can be viewed as a Bose-Einstein condensation of magnons [68, 69, 70, 71, 72, 73]. The quantum fluctuation of low-lying excitations for these quantum spin systems are characterized by spin waves which reveal bosonic signature. In this way the strongly coupled spin ladder with magnon excitations in high magnetic field can be mapped onto a one-dimensional XXZ Heisenberg model with an effective magnetic field. From this mapping, the

critical fields are given by $H_{c1} \approx J_{\perp} - J_{\parallel}$ and $H_{c2} \approx J_{\perp} + 2J_{\parallel}$ [63, 64], which agree rather well with experiments [20].

Considerable interest has been generated by fractional magnetization plateaux, which have been found in Shastry-Sutherland dimer systems [74, 75, 76] and some spin organic ferrimagnetic ladders [77, 78, 79]. Theoretical studies and numerical results suggest that magnetization plateaux exist in a mixed spin ladder [80, 81, 82] and the mixed spin- $(\frac{1}{2}, 1)$ chains [83, 84, 85, 86, 87, 88, 89, 90]. It was concluded that for certain strong rung coupling values, there exist magnetization plateaux at $M^z = 0.5$ and at $M^z = 1$, but no plateaux for negative (ferromagnetic) rung coupling values. In the strong coupling limit, the mixed spin ladder can be viewed as a ferrimagnetic chain which displays unusual quantum effects at low temperatures.

1.3 Integrable ladder models

Haldane's conjectured universal properties of the spin- S Heisenberg antiferromagnet depending on whether $2S$ is odd or even have been recognized in many disordered spin liquid systems, such as in spin ladders, mixed spin ladders and alternating spin chains. The spin liquid systems have a finite correlation length and a spin gap at zero temperature. The ground state is a spin singlet. The lowest spin triplet excitations have an energy gap due to the finite correlation length. In this context, Nersisyan and Tsvetlik [91] predicted a different gapped phase for a generalised two-leg spin- $\frac{1}{2}$ ladder model with a strong four-spin interaction term (the biquadratic interaction strength $|V|$ is very large [91]). This model includes the conventional two-leg Heisenberg spin- $\frac{1}{2}$ ladder and the integrable spin ladder model based on $su(4)$ algebra symmetry [92] as special cases, i.e., $V = 0$ and $|V| = 4J_{\parallel}$, respectively. In the case of weak biquadratic interaction ($|V|$ very small), the generalised Heisenberg ladder model has the same Haldane spin liquid phase as that of the conventional spin ladder. However, for strong enough biquadratic interaction this generalized ladder model exhibits a spontaneous dimerization phase which is different from the Haldane spin liquid gapped phase. The physical importance of the model has been subsequently noted [93].

From the theoretical perspective, these ladder models cannot be solved exactly, in contrast to the spin- $\frac{1}{2}$ Heisenberg chain. Thus their thermal and magnetic properties are not accessible via exact methods. In order to get a handle on the physical properties, some integrable extensions of the Heisenberg ladders have been constructed [92, 94, 95, 96, 97, 98, 99, 114, 115, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113]. These models include an integrable ladder based on the $su(4)$ algebra [92] and integrable n -leg ladder models [96, 97, 98, 99, 114, 115] among a number of variants. At first glance, due to the complicated spin-spin interactions along the legs and rungs, it appears

that none of these models can be used to predict physical properties for direct comparison with experimental data. Indeed, the application of the integrable ladder models to ladder materials should be taken with caution. In this article we focus on the calculation and study of the exact thermal and magnetic properties of the integrable ladder models and attempt to fit these properties to the experimental data for some known strong coupling ladder compounds by setting aside the issues regarding the applicability of the integrable Hamiltonian to those materials, in particular the effect of the biquadratic interaction term. We demonstrate that under certain conditions, namely

$$J_{\perp} \gg J_{\parallel} \quad \text{and} \quad K_B T > J_{\parallel} \quad (1)$$

the integrable ladder models may be used to study the thermal and magnetic properties of ladder materials with strong rung coupling. However, at low temperatures the biquadratic interaction term in the integrable models may lead to discrepancies with the physics of the ladder materials. These discrepancies are minimal if $J_{\perp} \gg J_{\parallel}$. We point out that the good agreement between the theoretical predictions and the experimental results for macroscopic quantities such as the magnetization, the susceptibility and the specific heat do not imply that the materials considered have the integrable Hamiltonian structure. For determining the precise structure of the materials more physical analysis, such as dynamical structure and dispersion in low-lying excitations, should be carried out in addition to the study of the thermal and magnetic properties. At high temperatures, the thermodynamics of the compounds can also be modelled by a rung-dimer system [185]. However, the dimer model gives poor agreement with experimental results at low temperatures. For the dimer model, it appears necessary to include Dzyaloshinskii-Moriya interaction terms in order to better explain the experimental behaviour [186].

The integrable ladder model based on the $su(4)$ algebra [92] appears to be a good candidate [8, 116, 117] for studying the ladder compounds, since its Hamiltonian is that of the standard Heisenberg ladder with an additional biquadratic spin interaction. The physical interpretation of the biquadratic spin interaction term is of various kinds. In the continuum limit it represents an interchain coupling of spin-dimerization fields which therefore influence the low-energy properties of the spin ladder [91]. In the strong coupling limit, the effective biquadratic spin-spin coupling arises from virtual electron transitions between neighbouring magnetic atoms. This coupling is in general very small in spin chain systems [118], smaller than for example the quadratic interaction term. In principle, the strength of the biquadratic interaction in ladder materials might be accurately determined through calculation of exchange integrals.

For strong rung coupling, i.e., $4J_{\parallel} \ll J_{\perp}$, the spin-spin exchange interaction is dominated by the strong rung interaction. It follows that the contribution

from the interaction along the ladder legs, including the biquadratic term, to the low-temperature physics is much less than the contribution from the rung interaction. However, the leg interactions and the biquadratic spin interactions do cause a shift in the critical field values. This kind of shift in the critical field values can be balanced by adjusting the interaction strengths. We shall see clearly that the values of the coupling constants $J_{\parallel}$ for the various compounds determined from the integrable model are always smaller than the values fixed by the standard Heisenberg spin ladder, as a result of including the biquadratic interaction term. The integrable spin ladder model provides a consistent and elegant way to obtain the ground state and thermodynamic properties of the strongly coupled ladder compounds, i.e., with $4J_{\parallel} \ll J_{\perp}$. We emphasise again that we set aside any issues regarding the reality of the biquadratic interaction term. The advantage of the integrable model approach is that it opens up the exact calculation of finite temperature thermodynamic properties via the well established methods developed for integrable systems [4, 5], including the more recently developed high-temperature expansion method reviewed in this article.

The interaction $J_{\parallel}$ plays an essential role in opening up a Luttinger liquid magnetic phase between the singlet and fully-polarized phases for $H_{c1} < H < H_{c2}$. Although the physical properties are not sensitive to the value of $J_{\parallel}$ at large temperatures, $J_{\parallel}$ has a significant influence on the low temperature behaviour. It is argued that for the integrable model the collective effect from the biquadratic interaction and the exchange interaction along the ladder legs are equivalent to the pure Heisenberg type interaction in the standard Heisenberg spin ladder model for the strong coupling region $4J_{\parallel} \ll J_{\perp}$. The coupling constants can be fixed by an overall fit of the critical fields and thermodynamic properties with the experimental results. In this way the integrable model is seen to exhibit similar critical behaviour, i.e., in the same universality class, in the correlation functions, magnetization, susceptibility, specific heat etc to the non-integrable Heisenberg ladder, which has so far been used to examine spin ladder materials [20].

The Thermodynamic Bethe Ansatz (TBA) [119, 120] has been widely applied to many physical problems, e.g., to the Heisenberg magnet [120, 121], the Hubbard model [122, 123], the supersymmetric t - J model [124, 125, 126, 127] and the Kondo problem [128]. It has most recently evolved into the exact High Temperature Expansion (HTE) method [129, 130, 131, 132, 133]. The key ingredients of the HTE method are the Quantum Transfer Matrix (QTM) [134, 135, 136, 137, 138, 139, 140, 141, 142, 143] and a functional relation called the T -system [144, 145, 146], from which one derives nonlinear integral equations which can be solved in an exact perturbative fashion. To date this approach has been applied to the Heisenberg model [129], the $osp(1|2s)$ model [130], the $su(N)$ Uimin-Lai-Sutherland model [131], the higher spin Heisenberg model

[147], the $su(N)$ Perk-Schultz model [148] and the $su(m|n)$ Perk-Schultz model [149]. In particular, in this way, i.e., via the HTE expansion, it has been demonstrated that the integrable $su(4)$ ladder model can be used to study the thermodynamics and magnetic properties of the strongly coupled ladder compounds [8].

For strongly coupled ladders, the rung coupling $J_\perp$ can overwhelm the intrachain interaction $J_\parallel$ such that a pair of spin- S magnetic ions along each rung forms an effective spin- $2S$ ion, allowing the strongly coupled ladders to be mapped to one-dimensional spin chains. The integrable ladder models based on $su(N)$ symmetry provide a tunable way to describe experimental compounds for which the rung coupling dominates the exchange interaction along the legs. In a certain basis, the rung interaction terms are diagonal while the basis maintains the $su(N)$ permutator exchange interaction along the legs. More precisely, the integrable ladder models based on $su(N)$ symmetry can be mapped to one-dimensional $su(N)$ [8, 96, 97, 98, 99] chains with additional chemical potentials. Consequently, the thermal and magnetic properties can be systematically derived from the exact TBA and HTE approaches.

The TBA method is seen to be most convenient for predicting critical fields of relevance to quantum phase transitions in ladder compounds [116, 117, 150, 151, 152], spin chains [153, 154] with strong single-ion anisotropies [155, 156] and spin-orbital models [157, 158]. It has been shown [116, 117, 151] that in the strong coupling region the integrable two-leg spin- $\frac{1}{2}$ ladder model exhibits three quantum phases:

- (i) a gapped phase in the regime $H < H_{c1} = J_\perp - 4J_\parallel$,
- (ii) a fully polarized phase for $H > H_{c2} = J_\perp + 4J_\parallel$,
- (iii) a Luttinger liquid magnetic phase in the regime $H_{c1} < H < H_{c2}$.

The critical behaviour in the vicinity of the critical points H_{c1} and H_{c2} is seen to be of the Pokrovsky-Talapov type. On the other hand, the HTE method gives the temperature-dependent free energy, from which physical properties such as the magnetic susceptibility and the specific heat can be derived [8, 152]. Indeed, as we shall discuss here, in certain regimes, the integrable two-leg ladder with strong rung coupling [8, 152] describes some experimental compounds, e.g., $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$ [42], $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$ [44, 45], $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$ [47], as well as the double spin chain systems KCuCl_3 [?, ?, 50, 51] TiCuCl_3 [50, 57, 58, 60], organic polyradical ladders BIP-BNO [159, 160], $[\text{Cu}_2(\text{C}_2\text{O}_2)(\text{C}_{10}\text{H}_8\text{N}_2)_2](\text{NO}_3)_2$ [161] and the ferrimagnetic mixed spin ladder PNNBNO [77, 78, 79].

1.4 Key results and outline

In this article we review the calculation of the physical properties of an integrable two-leg spin- $\frac{1}{2}$ ladder and an integrable mixed spin- $(\frac{1}{2}, 1)$ ladder. For the integrable spin- $\frac{1}{2}$ ladder with strong rung coupling the singlet ground state is separated from the lowest magnon (triplet) excitation by a finite energy gap. Notably, the values for the energy gap, $\Delta = J_{\perp} - 4J_{\parallel}$, and the critical points, $H_{c1} = J_{\perp} - 4J_{\parallel}$ and $H_{c2} = J_{\perp} + 4J_{\parallel}$, derived from the TBA are in excellent agreement with the available experimental results for strong coupling ladder compounds. The compounds discussed are $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$ [42], $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$ [44, 45], $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$ [47], the organic polyradical ladders BIP-BNO [159, 160] and $[\text{Cu}_2(\text{C}_2\text{O}_2)(\text{C}_{10}\text{H}_8\text{N}_2)_2](\text{NO}_3)_2$ [161]. The finite temperature thermal and magnetic properties are examined for these compounds via the exact HTE, with good overall agreement between the theoretical predictions and the experimentally measured thermal and magnetic properties.

For the integrable mixed spin- $(\frac{1}{2}, 1)$ ladder, the ground state lies in a gapless phase and a one-third saturation magnetization plateau occurs as the rung coupling exceeds $J_{\perp} > \frac{4}{3}J_{\parallel} \ln 2$. In the absence of a magnetic field the model exhibits three quantum phases associated with doublets, quadruplets and $su(6)$ symmetry. The fractional plateau corresponding to a fully-polarized doublet state opens at the critical field H_{c1} and vanishes at the critical field H_{c2} . If the magnetic field is greater than H_{c3} , the quadruplets are fully polarized. The phase diagram is reminiscent of the spin- $\frac{3}{2}$ chain [153, 154]. The magnetic properties of the organic mixed ferrimagnetic ladder compound PNNBNO are examined via the HTE.

The ground state properties of two integrable spin-orbital models are also treated via the TBA method, from which it is seen that the single-ion anisotropy and orbit splitting field can trigger a magnetization plateau with respect to different Landé factors with spin and orbital degrees of freedom [157, 158]. The magnetization for spin and orbital degrees of freedom is also calculated numerically from the TBA equations.

The article is organised as follows. In section 2, we review the two integrable spin ladder models – a two-leg spin- $\frac{1}{2}$ ladder and a mixed spin- $(\frac{1}{2}, 1)$ ladder – along with their Bethe Ansatz solutions. In section 3, we discuss the TBA equations for the two-leg spin- $\frac{1}{2}$ ladder and the investigation of the ground state properties via the TBA equations at zero temperature. The exact and resulting numerical calculations for the magnetization and susceptibility are treated in detail. The Quantum Transfer Matrix method is reviewed in section 4, along with the derivation of the nonlinear integral equations in terms of the T -system. It is then shown how the free energy is derived from the HTE. The results are then applied in section 5 to examine the

thermal and magnetic properties of the strong coupling ladder compounds $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$, $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$, $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$, and the organic polyradical ladders BIP-BNO and $[\text{Cu}_2(\text{C}_2\text{O}_2)(\text{C}_{10}\text{H}_8\text{N}_2)_2](\text{NO}_3)_2$. In section 6, the same approach is applied to the mixed spin- $(\frac{1}{2}, 1)$ ladder with a discussion of the ladder compound PNNBNO. Section 7 is devoted to the study of the magnetic properties of the spin-orbital model. A concluding discussion is given in section 8.

It should be noted that readers more interested in the physical properties of the ladder compounds, rather than their detailed calculation, may choose to skip sections 3 and 4. In any case the relevant results are collected at the beginning of section 5 on the comparison of the thermal and magnetic properties with the experimental data. Conversely, readers more interested in the mathematical methods may prefer to concentrate on sections 3 and 4.

2 Integrable spin ladder models

The general two-leg ladder configuration is depicted in figure 2. The two-leg Heisenberg spin- $\frac{1}{2}$ ladder model is defined by the Hamiltonian [18, 20, 63]

$$\mathcal{H} = J_{\parallel} \sum_{j=1}^L (\vec{S}_j \cdot \vec{S}_{j+1} + \vec{T}_j \cdot \vec{T}_{j+1}) + J_{\perp} \sum_{j=1}^L \vec{S}_j \cdot \vec{T}_j - \mu_B g H \sum_{j=1}^L (S_j^z + T_j^z). \quad (2)$$

Here $\vec{S}_j = (S_j^x, S_j^y, S_j^z)$ and $\vec{T}_j = (T_j^x, T_j^y, T_j^z)$ are spin- $\frac{1}{2}$ operators acting on site j . For example, $\vec{S}_j = \frac{1}{2}\vec{\sigma}_j$, where $\vec{\sigma}_j = (\sigma_j^x, \sigma_j^y, \sigma_j^z)$ are Pauli matrices. The essential parameters are the rung coupling $J_{\perp}$, the intrachain coupling $J_{\parallel}$ and the external magnetic field H . The Bohr magneton is μ_B and $g = g_s = g_t$ is the Landé factor. There are L rungs and periodic boundary conditions, $\vec{S}_{L+1} = \vec{S}_1$ and $\vec{T}_{L+1} = \vec{T}_1$, are imposed.

Figure 2. The two-leg spin ladder. In general, sites on the lower (upper) leg carry spin- S (T) with g_s (g_t) the Landé factor along the leg. $J_{\parallel}$ is the intrachain or leg coupling and $J_{\perp}$ is the interchain or rung coupling.

This model has been extensively studied via numerical methods [18, 162,

163, 164, 27], perturbative field theory [63, 64, 67, 165, 168] and transfer matrix methods [66]. Some essential physics of the model can be obtained from the strong coupling region $J_\perp \gg J_\parallel$. Consider the more general spin- S ladder. Then in this limit the ladder effectively becomes a spin- $2S$ chain with single-ion anisotropy. The physics of the ladder/chain equivalence holds even for weak coupling, but this is by no means obvious. The gapped phase persists for arbitrary rung coupling, with the spin-spin correlation decaying exponentially. The analogy between the physics of the spin chain with $2S$ even/odd and the spin ladder with even/odd number of legs is well described by the quantum field theoretic approach [166, 167, 168]. Both the antiferromagnetic Heisenberg spin chain and the ladder can be mapped to the nonlinear sigma models. The field theory approach thus gives a unified description of the Heisenberg chains and ladders. In this framework the gapped and gapless phases of the spin chains and ladders are governed by the topological term $\theta = 0$ or π , respectively, in the nonlinear sigma model [169, 168].

2.1 The integrable two-leg spin- $\frac{1}{2}$ ladder

The simplest integrable spin ladder is defined by the Hamiltonian [92]

$$\mathcal{H} = J_\parallel \mathcal{H}_{\text{leg}} + J_\perp \sum_{j=1}^L \vec{S}_j \cdot \vec{T}_j - \mu_B g H \sum_{j=1}^L (S_j^z + T_j^z) \quad (3)$$

where

$$\mathcal{H}_{\text{leg}} = \sum_{j=1}^L \left(\vec{S}_j \cdot \vec{S}_{j+1} + \vec{T}_j \cdot \vec{T}_{j+1} + 4(\vec{S}_j \cdot \vec{S}_{j+1})(\vec{T}_j \cdot \vec{T}_{j+1}) \right). \quad (4)$$

Periodic boundary conditions, $\vec{S}_{L+1} = \vec{S}_1$, $\vec{T}_{L+1} = \vec{T}_1$, are applied. This integrable Hamiltonian contains a biquadratic term, which minimises the Haldane phase [91, 116, 117] and causes a shift of the critical value of the rung coupling $J_\perp$ at which the gap vanishes (recall that the gap vanishes at zero rung coupling for the Heisenberg ladder). The other key feature of the model is that it has the same magnetic field and rung interaction terms as the standard Heisenberg ladder (2). In the absence of symmetry breaking potentials, the dispersion of the low-lying excitations is entirely caused by the leg interaction. However, symmetry breaking potentials, such as rung interaction or external field, result in different band fillings such that the lowest spin excitation is gapped. The two-body and biquadratic interactions along the legs are effectively quenched by the strong rung singlet. The model thus lies in the same

phase as the standard Heisenberg ladder.

The critical behaviour of the model is determined by the competition between the rung and leg couplings and the magnetic field H . A key factor in the integrability of this Hamiltonian is that $\mathcal{H}_{\text{leg}}$ is (up to a constant) simply the permutation operator corresponding to the $su(4)$ algebra [114, 115]. This can be seen by performing a change of basis to the states

$$\begin{aligned} |1\rangle &= \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle), |2\rangle = |\uparrow\uparrow\rangle \\ |3\rangle &= \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle), |4\rangle = |\downarrow\downarrow\rangle \end{aligned} \quad (5)$$

where state $|1\rangle$ denotes the rung singlet and the remaining three states denote the triplet components. Here we have set $|\uparrow\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ and $|\downarrow\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$. Thus $|\uparrow\rangle\langle\uparrow| = \frac{1}{2}(1 + \sigma^z)$, $|\downarrow\rangle\langle\downarrow| = \frac{1}{2}(1 - \sigma^z)$, $|\uparrow\rangle\langle\downarrow| = \sigma^+$ and $|\downarrow\rangle\langle\uparrow| = \sigma^-$. Note that in this new basis the leg part remains of the same form while the rung term becomes diagonal. The rung term reduces the $su(4)$ symmetry of $\mathcal{H}_{\text{leg}}$ to $su(3) \oplus u(1)$ symmetry under the action of the local chemical potential $J_{\perp}|1\rangle_j\langle 1|$. Switching on the magnetic field further breaks this symmetry due to Zeeman splitting. Moreover, the $su(3) \oplus u(1)$ symmetry does not survive if we consider different g factors along the two legs. Let g_t and g_s be these Landé factors along the upper and lower legs, respectively. Then the Hamiltonian reads [157, 158]

$$\mathcal{H} = J_{\parallel}\mathcal{H}_{\text{leg}} + J_{\perp} \sum_{j=1}^L \vec{S}_j \cdot \vec{T}_j - \mu_B H \sum_{j=1}^L (g_s S_j^z + g_t T_j^z) \quad (6)$$

where the local eigenbasis on the j th rung is given by

$$\begin{aligned} \phi_0 &= \frac{1}{\sqrt{1 + (y^{(-)})^2}} \left(|\uparrow\downarrow\rangle + y^{(-)} |\downarrow\uparrow\rangle \right), \quad \phi_1 = |\uparrow\uparrow\rangle \\ \phi_2 &= \frac{1}{\sqrt{1 + (y^{(+)})^2}} \left(|\uparrow\downarrow\rangle + y^{(+)} |\downarrow\uparrow\rangle \right), \quad \phi_3 = |\downarrow\downarrow\rangle \end{aligned} \quad (7)$$

with

$$y^{(\pm)} = (g_s - g_t)\mu_B H / J_{\perp} \pm \sqrt{1 + (g_s - g_t)^2 \mu_B^2 H^2 / J_{\perp}^2}. \quad (8)$$

In this procedure it is important to note that the leg content, $\mathcal{H}_{\text{leg}}$, equation (4), of the Hamiltonian is invariant under any change of rung eigenbasis. It is also invariant under any choice of reference state for the application of the algebraic Bethe ansatz, while the rung and the field terms are altered by these

changes. The validity for reordering the basis arises from the fact that the intrachain interaction is the permutation operator, which is independent of the choice of basis for the vector space $V = V_1 \oplus V_2$. On the other hand, the rung interaction and magnetic field vary the energy levels of the eigenbasis states following from equations (5) and (7).

Generally speaking, the difference between g_t and g_s is often very small and even negligible for the isotropic two-leg ladder model, but this may be different for the spin-orbital models [170,171,172]. For simplicity, unless otherwise stated, we consider here the isotropic ladder model (3) for the application of the TBA and HTE methods.

In section 4 it is shown that the integrable Hamiltonian (3) can be derived, up to an unimportant constant, by exploiting the spectrum parameter v and the row-to-row transfer matrix $t(v) = \text{tr}_0 R_{0,L}(v) R_{0,L-1}(v) \cdots R_{0,2}(v) R_{0,1}(v)$ via the relation

$$\mathcal{H} = J_{\parallel} \frac{d}{dv} \ln t(v)|_{v=0} - J_{\perp} \sum_{j=1}^L |1\rangle_j \langle 1|_j - \mu_B g H \sum_{j=1}^L (|2\rangle_j \langle 2|_j - |4\rangle_j \langle 4|_j) \quad (9)$$

in terms of the underlying $su(4)$ R -matrix, which is simply $R(v) = vI + \mathcal{P}$, where $\mathcal{P}$ is the 16×16 permutation operator (cf. equation (79)). After some algebra, the energy spectrum can be obtained from relation (9) as [116,117]

$$\mathcal{E} = -J_{\parallel} \sum_{i=1}^{M_1} \frac{1}{(v_i^{(1)})^2 + \frac{1}{4}} - J_{\perp} N_0 - \mu_B g (N_+ - N_-) H \quad (10)$$

in which N_0 denotes the number of rung singlets and N_+ and N_- denotes the number of the triplet components $|2\rangle$ and $|4\rangle$, respectively.

The number M_1 appearing in the energy spectrum (10) is the number of Bethe roots $v_i^{(1)}$ which satisfy the $r = 3$ case of the general $su(r+1)$ Bethe equations

$$\prod_{i=1}^{M_{k-1}} \frac{v_j^{(k)} - v_i^{(k-1)} + \frac{1}{2}i}{v_j^{(k)} - v_i^{(k-1)} - \frac{1}{2}i} = \prod_{\substack{l=1 \\ l \neq j}}^{M_k} \frac{v_j^{(k)} - v_l^{(k)} + i}{v_j^{(k)} - v_l^{(k)} - i} \prod_{l=1}^{M_{k+1}} \frac{v_j^{(k)} - v_l^{(k+1)} - \frac{1}{2}i}{v_j^{(k)} - v_l^{(k+1)} + \frac{1}{2}i} \quad (11)$$

obtained by application of the nested Bethe Ansatz [2, 9, 10, 11]. Here $k = 1, 2, \dots, r$ and $j = 1, \dots, M_k$, with the conventions $v_j^{(0)} = v_j^{(r+1)} = 0$, $M_{r+1} = 0$ and $M_0 = L$.

If $g_s \neq g_t$, the corresponding energy is given by [157, 158]

$$\begin{aligned} \mathcal{E} = & -J_{\parallel} \sum_{i=1}^{M_1} \frac{1}{(v_i^{(1)})^2 + \frac{1}{4}} - \frac{1}{2} J_{\perp} \left[1 + \sqrt{1 + (g_s - g_t)^2 h^2} \right] N_{\phi_0} \\ & - \frac{1}{2} \mu_B (g_s + g_t) H N_{\phi_1} + \frac{1}{2} \mu_B (g_s + g_t) H N_{\phi_3} \\ & - \frac{1}{2} J_{\perp} \left[1 - \sqrt{1 + (g_s - g_t)^2 h^2} \right] N_{\phi_2} \end{aligned} \quad (12)$$

with $h = \mu_B H / J_{\perp}$. In this case N_{ϕ_a} ($a \in \{0, 1, 2, 3\}$) is the number of ϕ_a states.

2.2 The integrable mixed spin- $(\frac{1}{2}, 1)$ ladder

Recalling figure 2, the integrable mixed spin- $(\frac{1}{2}, 1)$ ladder model is defined by the Hamiltonian [114, 115, 150]

$$\mathcal{H} = J_{\parallel} \mathcal{H}_{\text{leg}} + J_{\perp} \sum_{j=1}^L \vec{T}_j \cdot \vec{S}_j - \mu_B H \sum_{j=1}^L (g_t T_j^z + g_s S_j^z) \quad (13)$$

$$\mathcal{H}_{\text{leg}} = \sum_{j=1}^L \left(\frac{1}{2} + 2 \vec{T}_j \cdot \vec{T}_{j+1} \right) \left(-1 + \vec{S}_j \cdot \vec{S}_{j+1} + (\vec{S}_j \cdot \vec{S}_{j+1})^2 \right). \quad (14)$$

For this model $\vec{T}_j$ remain spin- $\frac{1}{2}$ operators but now $\vec{S}_j$ are spin-1 operators and we consider general Landé factors g_t and g_s . Periodic boundary conditions are again imposed and L is the number of rungs.

By construction $\mathcal{H}_{\text{leg}}$ defined in (14) is the permutation operator with $su(6)$ algebraic symmetry. In this case the rung term in (13) breaks the $su(6)$ symmetry into an $su(4) \oplus su(2)$ symmetry, i.e., quadruplet plus doublet symmetry. Now changing the fundamental basis of $su(6)$ into rung quadruplet and doublet states (via Clebsch-Gordan decomposition) results in the six-dimensional state space splitting into the direct sum of quadruplets and doublets with regard to the rung interaction. The projectors onto the doublet and quadruplet subspace are given by

$$\mathcal{P}_d = -\frac{2}{3}(\vec{T} \cdot \vec{S} - \frac{1}{2}), \quad \mathcal{P}_q = \frac{2}{3}(\vec{T} \cdot \vec{S} + 1). \quad (15)$$

Although the magnetic field preserves the integrability of the leg part of the Hamiltonian, the different g -factors on each leg break the doublet/quadruplet basis for the Hamiltonian (13) due to Zeeman splitting. Fortunately, there is

another basis,

$$\begin{aligned}\psi_{\frac{1}{2}}^{(\pm)} &= \frac{1}{\sqrt{1 + (y_{\frac{1}{2}}^{(\pm)})^2}} \left(|1, -\frac{1}{2}\rangle + y_{\frac{1}{2}}^{(\pm)} |0, \frac{1}{2}\rangle \right) \\ \psi_{-\frac{1}{2}}^{(\pm)} &= \frac{1}{\sqrt{1 + (y_{-\frac{1}{2}}^{(\pm)})^2}} \left(|-1, \frac{1}{2}\rangle + y_{-\frac{1}{2}}^{(\pm)} |0, -\frac{1}{2}\rangle \right)\end{aligned}\quad (16)$$

$$\begin{aligned}\psi_{\frac{3}{2}} &= |1, \frac{1}{2}\rangle \\ \psi_{-\frac{3}{2}} &= |-1, -\frac{1}{2}\rangle\end{aligned}\quad (17)$$

that diagonalises the rung and magnetization terms simultaneously. Here the quantities $y_a^{(\pm)}$ are given by

$$y_a^{(\pm)} = a\sqrt{2}[(g_s - g_t)h' + a] \pm \sqrt{1 + \frac{1}{2}(g_s h' - g_t h' + a)^2} \quad (18)$$

where $a = \pm\frac{1}{2}$ and $h' = \mu_B H / J_{\perp}$. Further

$$|1\rangle = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, |0\rangle = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}, |-1\rangle = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, |\frac{1}{2}\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, |-\frac{1}{2}\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \quad (19)$$

with $|b, a\rangle = |b\rangle \otimes |a\rangle$. If $g_s = g_t$, the basis states $\psi_{\frac{1}{2}}^{(-)}$ and $\psi_{-\frac{1}{2}}^{(-)}$ reduce to the doublet, with the other states reducing to the quadruplet. It follows that the leg and rung parts of the Hamiltonian (14) are given by the relation

$$\mathcal{H} = J_{\parallel} \frac{d}{dv} \ln t(v)|_{v=0} + \sum_{j=1}^L \sum_{\alpha, \beta} \mu_{\beta}^{(\alpha)} |\psi_{\beta}^{(\alpha)}\rangle_j \langle \psi_{\beta}^{(\alpha)}|_j + \text{constant} \quad (20)$$

associated with the row-to-row transfer matrix. Here $\alpha = +, 0, -$ and $\beta = \pm\frac{1}{2}, \pm\frac{3}{2}$, with $\psi_{\beta}^{(0)} = \psi_{\beta}$. The chemical potentials $\mu_{\beta}^{(\alpha)}$ are given in (22) below.

The eigenspectrum is obtained from relation (20) and the Bethe Ansatz to be [150]

$$\mathcal{E} = -J_{\parallel} \sum_{i=1}^{M_1} \frac{1}{v_i^{(1)2} + \frac{1}{4}} + \mathcal{E}_{\perp+h} \quad (21)$$

where the Bethe roots $v_i^{(1)}$ satisfy the Bethe equations (11) with $r = 5$. The energy contribution from the rung interaction and the magnetic field terms is given by

$$\begin{aligned}
\mathcal{E}_{\perp+h} = & \left[-\frac{1}{4}J_{\perp} - \frac{1}{2}g_s\mu_B H - \frac{1}{\sqrt{2}}J_{\perp}\sqrt{1 + \frac{1}{2}(g_s h' - g_t h' + \frac{1}{2})^2} \right] N_{\frac{1}{2}}^{(-)} \\
& + \left[-\frac{1}{4}J_{\perp} + \frac{1}{2}g_s\mu_B H - \frac{1}{\sqrt{2}}J_{\perp}\sqrt{1 + \frac{1}{2}(g_s h' - g_t h' - \frac{1}{2})^2} \right] N_{-\frac{1}{2}}^{(-)} \\
& + \left[\frac{1}{2}J_{\perp} - (\frac{1}{2}g_t + g_s)\mu_B H \right] N_{\frac{3}{2}} \\
& + \left[-\frac{1}{4}J_{\perp} - \frac{1}{2}g_s\mu_B H + \frac{1}{\sqrt{2}}J_{\perp}\sqrt{1 + \frac{1}{2}(g_s h' - g_t h' + \frac{1}{2})^2} \right] N_{\frac{1}{2}}^{(+)} \\
& + \left[-\frac{1}{4}J_{\perp} + \frac{1}{2}g_s\mu_B H + \frac{1}{\sqrt{2}}J_{\perp}\sqrt{1 + \frac{1}{2}(g_s h' - g_t h' - \frac{1}{2})^2} \right] N_{-\frac{1}{2}}^{(+)} \\
& + \left[\frac{1}{2}J_{\perp} + (\frac{1}{2}g_t + g_s)\mu_B H \right] N_{-\frac{3}{2}}
\end{aligned} \tag{22}$$

In the above equation, $N_{\pm\frac{1}{2}}^{(\pm)}$ and $N_{\pm\frac{3}{2}}^{(\pm)}$ are the occupation numbers of the corresponding states and $h' = \mu_B H / J_{\perp}$.

3 Thermodynamic Bethe Ansatz

3.1 Derivation of the TBA equations

In this section we turn to the study of the ground state properties and the phase diagram of the integrable two-leg spin- $\frac{1}{2}$ ladder (3) by means of the Thermodynamic Bethe Ansatz (TBA). In the thermodynamic ($L \rightarrow \infty$) limit, the roots of the Bethe equations for the ground state are real. At zero temperature there are no holes in the ground state root distribution. Yang and Yang [119] introduced the TBA in treating the thermodynamics of the one-dimensional boson model with delta function interaction, where the elementary excitations involve moving quasimomenta out of the Dirac sea. In general complex conjugate pairs of Bethe roots form bound states of two magnons. The string hypothesis has been developed to classify the many permissible bound state solutions to the Bethe equations, originally for the Heisenberg chain [120], the one-dimensional Hubbard model [122], the supersymmetric $t - J$ model [124, 125, 126, 127], Kondo problems [128] and the higher-spin Heisenberg chain [173] among others. Recall that the Bethe equations (11) for the ladder model (3) consist of a set of three coupled equations with Bethe Roots of three different colours, $v_i^{(k)}$, $k = 1, 2, 3$. Taking the thermodynamic

limit [119, 120, 174] results in the string solutions

$$v_{\alpha_k j}^{(k)n} = v_{\alpha_k}^{(k)n} + \frac{1}{2}i(n+1-2j) \quad (23)$$

where $j = 1, \dots, n$ and $\alpha_k = 1, \dots, N_n^{(k)}$. Here $v_{\alpha_k}^{(k)n}$, $k = 1, 2, 3$, are the positions on the real axis of the centre of an n -string, where n is the string length in each colour. There are $N_n^{(k)}$ strings of the n -string form. The number of n -string $N_n^{(k)}$ satisfy the relation $N^{(k)} = \sum_{n=1}^{\infty} n N_n^{(k)}$, where $N^{(k)}$ is the total number of Bethe roots of colour k .

It is assumed that the distributions of Bethe roots are dense along the real axis. The missing roots of each colour k are the holes, with positions $v_{\alpha_k}^{(k)h}$ on the real axis. The distribution densities of n -string roots, $\rho_n^{(k)}(v)$, and holes, $\rho_n^{(k)h}(v)$, are defined to be

$$\rho_n^{(k)}(v) = \lim_{L \rightarrow \infty} \frac{1}{L(v_{\alpha_k+1}^{(k)n} - v_{\alpha_k}^{(k)n})} \quad (24)$$

$$\rho_n^{(k)h}(v) = \lim_{L \rightarrow \infty} \frac{1}{L(v_{\alpha_k+1}^{(k)h} - v_{\alpha_k}^{(k)h})} \quad (25)$$

for the three colours $k = 1, 2, 3$.

Adopting the standard notation [173]

$$\begin{aligned} A_{nm}(\lambda) &= \delta(\lambda)\delta_{nm} + (1 - \delta_{nm})a_{|n-m|}(\lambda) + a_{n+m}(\lambda) \\ &\quad + 2 \sum_{l=1}^{\text{Min}(n,m)-1} a_{|n-m|+2l}(\lambda) \end{aligned} \quad (26)$$

$$a_{nm}(\lambda) = \sum_{l=1}^{\text{Min}(n,m)} a_{n+m+1-2l}(\lambda) \quad (27)$$

with $a_n(\lambda) = \frac{1}{2\pi} \frac{n}{n^2/4 + \lambda^2}$, the Bethe equations (11) can be transformed after a long though standard calculation into the form

$$\rho_n^{(1)h}(v) = a_n(v) - \sum_m (A_{nm} * \rho_m^{(1)})(v) + \sum_m (a_{nm} * \rho_m^{(2)})(v) \quad (28)$$

$$\rho_n^{(2)h}(v) = - \sum_m (A_{nm} * \rho_m^{(2)})(v) + \sum_m (a_{nm} * (\rho_m^{(1)} + \rho_m^{(3)}))(v) \quad (29)$$

$$\rho_n^{(3)h}(v) = - \sum_m (A_{nm} * \rho_m^{(3)})(v) + \sum_m (a_{nm} * \rho_m^{(2)})(v) \quad (30)$$

where $*$ denotes the convolution integral $(f * g)(\lambda) = \int_{-\infty}^{\infty} f(\lambda - \lambda')g(\lambda')d\lambda'$.

In order to find the equilibrium state of the system at a fixed temperature T and external magnetic field, the free energy $F = E - TS - \mu_B g M^z$ is minimised with respect to the densities. To this end, the energy per site can be written as

$$\mathcal{E}/L = -J_{\parallel} \sum_{n=1}^{\infty} \int_{-\infty}^{\infty} dv a_n(v) \rho_n^{(1)}(v) - J_{\perp} N_0 \quad (31)$$

in terms of the densities of roots and holes. Following [119] the total entropy of the system is given by

$$S = \sum_{n=1}^{\infty} \int_{-\infty}^{\infty} dv \left(\sum_{k=1}^3 (\rho_n^{(k)}(v) + \rho_n^{(k)h}(v)) \ln(\rho_n^{(k)}(v) + \rho_n^{(k)h}(v)) - \rho_n^{(k)}(v) \ln \rho_n^{(k)}(v) - \rho_n^{(k)h}(v) \ln \rho_n^{(k)h}(v) \right) \quad (32)$$

with magnetization

$$M^z = \mu_B g (N_+ - N_-). \quad (33)$$

Minimizing the free energy, i.e., $\delta F = 0$, and making use of the equations (28)-(30) gives the TBA equations

$$\begin{aligned} \ln(1 + \eta_n^{(k)}(v)) &= \frac{1}{T} g_n^{(k)}(v) + \sum_{m=1}^{\infty} A_{nm} * \ln(1 + \eta_m^{(k)-1})(v) \\ &\quad - \sum_{m=1}^{\infty} a_{nm} * \ln(1 + \eta_m^{(k-1)-1})(v) \\ &\quad - \sum_{m=1}^{\infty} a_{nm} * \ln(1 + \eta_m^{(k+1)-1})(v) \end{aligned} \quad (34)$$

in terms of the functions $\eta_n^{(k)}(v) = \rho_n^{(k)h}(v)/\rho_n^{(k)}(v)$. Henceforth for notational simplicity we will omit the argument v . The driving terms $g_n^{(k)}(v) = nx^{(k)} - \delta_{1,k} 2\pi a_n(v)$ appearing in the TBA equations (34) play a key role to be discussed further below. Here $x^{(k)}$ is the chemical potential for the colour k -branch.

The TBA equations are often written in terms of the dressed energies $\epsilon_n^{(k)}(v)$, defined via $\eta_n^{(k)}(v) = \exp(\epsilon_n^{(k)}(v)/T)$ for $k = 1, 2, 3$ with $\epsilon_n^{(0)}(v) = \epsilon_n^{(4)}(v) = 0$.

Specifically,

$$\begin{aligned} \epsilon_1^{(k)} &= g_1^{(k)} + T a_2 * \ln(1 + e^{-\epsilon_1^{(k)}/T}) + T(a_0 + a_2) \sum_{m=1}^{\infty} a_m * \ln(1 + e^{-\epsilon_{m+1}^{(k)}/T}) \\ &\quad - T \sum_{m=1}^{\infty} a_m * \left(\ln(1 + e^{-\epsilon_m^{(k-1)}/T}) + \ln(1 + e^{-\epsilon_m^{(k+1)}/T}) \right) \end{aligned} \quad (35)$$

with

$$\begin{aligned} \epsilon_n^{(k)} &= g_n^{(k)} + T a_1 * \ln(1 + e^{-\epsilon_{n-1}^{(k)}/T}) + T a_2 * \ln(1 + e^{-\epsilon_n^{(k)}/T}) \\ &\quad + T(a_0 + a_2) \sum_{m=n}^{\infty} a_{m-n} * \ln(1 + e^{-\epsilon_m^{(k)}/T}) \\ &\quad - T \sum_{m=n}^{\infty} a_{m-n+1} * \left(\ln(1 + e^{-\epsilon_m^{(k-1)}/T}) + \ln(1 + e^{-\epsilon_m^{(k+1)}/T}) \right) \end{aligned} \quad (36)$$

for $n > 1$. The dressed energies play the role of excitation energies measured from the Fermi energy level for each colour, and satisfy a Fermi-Dirac-like distribution. This can be seen from the ratio of the number of occupied vacancies to the total number of vacancies in the interval v to $v + dv$ for colour k . Namely

$$\frac{\rho_n^{(k)}(v)}{\rho_n^{(k)}(v) + \rho_n^{(k)h}(v)} = \frac{1}{1 + e^{\epsilon_n^{(k)}(v)}}. \quad (37)$$

The dressed energies $\epsilon_n^{(k)}(v)$ for $k = 1, 2, 3$ are monotonically increasing functions of $|v|$ and even, i.e., $\epsilon_n^{(k)}(v) = \epsilon_n^{(k)}(-v)$ with

$$\lim_{n \rightarrow \infty} \frac{\epsilon_n^{(k)}(v)}{n} = 2x^{(k)}.$$

In the above equations the driving terms $g_1^{(k)}$ and $g_n^{(k)}$ depend on the choice of the basis order due to the energy level splitting among the singlet and the triplet components with respect to the competition between the rung interaction and the magnetic field, see (10) and (12). It is worth noting that for the ladder Hamiltonian (3) the singlet rung state is energetically favoured when $J_{\perp} > 0$ (antiferromagnetic coupling), while for $J_{\perp} < 0$ (ferromagnetic coupling) the triplet rung state is energetically more favourable. Here we consider only the antiferromagnetic coupling regime, i.e., with $J_{\parallel} > 0$ and $J_{\perp} > 0$. Although the physics of the model doesn't depend on the basis order, the driving

terms vary the Fermi surfaces of each branch in different ways. It is most convenient to order the basis according to the energy levels of the singlet and triplet components which provides a natural order with respect to the band filling. For strong rung coupling there are only two components, the singlet and the lowest component of the triplet, which compete in the ground state. The other components induce a gap above the ground state. In this natural basis order, the TBA equations for the ground state reduce to one band with finite Fermi points.

Explicitly, in the strong coupling regime, i.e., $J_\perp \geq 4J_\parallel$ and $J_\perp > H$, the basis order is chosen as $(|1\rangle, |2\rangle, |3\rangle, |4\rangle)$, corresponding to the Bethe states with number N_1 of state $|1\rangle$, up to number N_4 of state $|4\rangle$. Here $N_1 = L - M_1$, $N_2 = M_1 - M_2$, $N_3 = M_2 - M_3$ and $N_4 = M_3$ (see equation (11)). The driving terms are thus given by

$$g_1^{(1)} = -J_\parallel 2\pi a_1 + J_\perp - \mu_B g H, \quad g_1^{(2)} = g_1^{(3)} = \mu_B g H. \quad (38)$$

The higher order driving terms are $g_n^{(1)} = n\mu_B g H$, $g_n^{(2)} = n g_1^{(2)}$ and $g_n^{(3)} = n g_1^{(3)}$. Subsequently, up to a constant, the free energy is

$$f(T, H) = -T \int_{-\infty}^{\infty} \sum_{n=1}^{\infty} a_n(v) \ln(1 + e^{-\epsilon_n^{(1)}(v)/T}) dv. \quad (39)$$

However, if $H > J_\perp$, the basis order can be taken to be $(|2\rangle, |1\rangle, |3\rangle, |4\rangle)$ for a simpler analysis of the TBA equations. The driving terms are then

$$g_1^{(1)} = -J_\parallel 2\pi a_1 - J_\perp + \mu_B g H, \quad g_1^{(2)} = J_\perp, \quad g_1^{(3)} = \mu_B g H \quad (40)$$

with the higher order driving terms remaining unchanged. In this case the free energy is

$$f(T, H) = -\mu_B g H - T \int_{-\infty}^{\infty} \sum_{n=1}^{\infty} a_n(v) \ln(1 + e^{-\epsilon_n^{(1)}(v)/T}) dv. \quad (41)$$

3.2 Ground state properties and phase diagram

We turn now to the ground state properties and the phase diagram of the integrable ladder model, as revealed by the analysis of the TBA equations. In the low-temperature limit $T \rightarrow 0$ only the negative part of the dressed energies $\epsilon^{(l)}$, denoted by $\epsilon^{(l)-} = \min\{\epsilon^{(l)}, 0\}$, contribute to the ground-state energy. Here we use the simplified notation $\epsilon^{(l)} = \epsilon_1^{(l)}$. The TBA equations

(35) then become

$$\begin{aligned}
\epsilon^{(1)} &= g_1^{(1)} - a_2 * \epsilon^{(1)-} + a_1 * \epsilon^{(2)-} \\
\epsilon^{(2)} &= g_1^{(2)} - a_2 * \epsilon^{(2)-} + a_1 * [\epsilon^{(1)-} + \epsilon^{(3)-}] \\
\epsilon^{(3)} &= g_1^{(3)} - a_2 * \epsilon^{(3)-} + a_1 * \epsilon^{(2)-}
\end{aligned} \tag{42}$$

where $g_1^{(a)}$, $a = 1, 2, 3$, are the driving terms with respect to the different basis orders given in (38) and (40).

In the absence of the symmetry-breaking chemical potential and magnetic field terms, the Fermi seas of the three bands are completely filled and have no Fermi surface, as depicted in upper left panel of figure 3. The Fermi sea of each band may be raised or lowered by the rung interaction and the external magnetic field, with spinon excitations created by flipping a spin. The chemical potential, rung interaction and magnetic field terms vary the Fermi surfaces at the bands, leading to interference effects between the two Fermi points.

In the antiferromagnetic regime ($J_\perp > 0$) it follows that if $H = 0$ the triplet excitation is massive, with the gap given by $\Delta = J_\perp - 4J_\parallel$. This configuration is depicted graphically in the upper right panel of figure 3, where all of the dressed energies are gapful. The critical point $J_c^+ = 4J_\parallel$ indicates a quantum phase transition from the three branches of the Luttinger liquid phase to the dimerised $u(1)$ phase. The magnetic field lifts the fermi seas of $\epsilon^{(2)}$ and $\epsilon^{(3)}$, which can be seen from the TBA equations (42).

For $J_\perp > J_c^+$, it can be shown that the two components of the triplet states, $|3\rangle$ and $|4\rangle$, do not enter into the groundstate for high magnetic field. However, the magnetic field shifts the energy level of the triplet component of $|2\rangle$ closer to the singlet groundstate. The gap can be deduced via the magnetic field H . The first critical field occurs at H_{c1} , where $g\mu_B H_{c1} = \Delta$, i.e., the effect of the magnetic field is to close the gap. The quantum phase transition is from a gapped to a gapless Luttinger phase. When $H > H_{c1}$ the triplet component of $|2\rangle$ begins to enter into the ground state with a finite susceptibility. The dressed energy configuration for this case is depicted in the lower left panel of figure 3. The dressed energies $\epsilon^{(2)}$ and $\epsilon^{(3)}$ are gapful, whereas $\epsilon^{(1)}$ has two Fermi points. The excitation energies are proportional to the momentum of particles. If $H > H_{IP} = J_\perp/\mu_B g$, the triplet component of $|2\rangle$ becomes the lowest energy level with driving terms (40). At the point $H = H_{IP}$, the magnetic field completely diminishes the rung interaction so that the Fermi sea of the dressed energy $\epsilon^{(1)}$ is completely filled, whereas the others are still gapful (see lower right panel of figure 3). In this way we see that the ground state is in a fully-polarized ferromagnetic state when the magnetic field is greater than $H_{c2} = J_\perp + 4J_\parallel$.

Figure 3. Depiction of the dressed energies for the $su(4)$ TBA equations (42). The four panels indicate the quantum phase transitions which occur in the ground state of the integrable ladder model (3) with strong rung coupling. The horizontal axis is the spectral parameter $v^{(k)}$ with the origin ($v^{(k)} = 0$) at the minima. The upper left panel shows the dressed energies in the absence of the symmetry-breaking chemical potential. In the presence of the chemical potential, the basis is reordered so that the Fermi surfaces of the dressed energies remain in the order $\epsilon^{(1)}$ lowest, $\epsilon^{(2)}$ second lowest and $\epsilon^{(3)}$ highest (see text).

The TBA predictions for the occurrence of critical fields H_{c1} and H_{c2} , along with their values, are in good agreement with the experimental results for several strong coupling ladder compounds [116,117], as will be discussed further in sections 3.3 and 5.

3.3 Analytical and numerical solutions of the TBA equations for the magnetization

The TBA equations (42) may be solved numerically [116,117,157,158,152,150] to study the magnetization of the integrable spin ladder model in detail. As a concrete example we take the strong coupling compound $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$ [42] for which the coupling constants can be used in the numerical calculations. This compound was recognized as a strong coupling ladder compound with the critical field values $H_{c1} \approx 8.3\text{T}$ and $H_{c2} \approx 10.4\text{T}$. For the integrable spin ladder model (3) the critical field values are $H_{c1} = J_{\perp} - 4J_{\parallel}$ and $H_{c2} = J_{\perp} + 4J_{\parallel}$. In this way reasonable values for the coupling constants $J_{\parallel}$ and $J_{\perp}$ can be suggested from the experimental critical field values. The g -factors are uniquely determined by experiment and are not free parameters in this approach. However, the coupling constants fixed by the critical fields only lead to a good fit

with the energy gap. In order to make a good overall fit for each of the key thermal and magnetic properties, the coupling constants should be fixed by the energy gap, the magnetization and the susceptibility. Once the coupling constants are fixed, all thermal and magnetic properties follow naturally. For this compound a fit to the experimental critical fields and the magnetization at different temperatures suggests the coupling constants $J_{\perp} = 13.3 \text{ K}$ and $J_{\parallel} = 0.2875 \text{ K}$, where we have used $g = 2.1$. The leg coupling constant $J_{\parallel}$ is smaller than for the pure Heisenberg model leg interaction due to the presence of the biquadratic term, which strengthens the overall leg interaction. Recall that the leg interaction (4) differs from that for the pure Heisenberg ladder model. As a result the leg coupling constant $J_{\parallel}$ for compounds determined from the integrable model (4) differs from that determined from the Heisenberg ladder model (2). In order to compare the difference between $J_{\parallel}$ determined by these two theoretical models, a scaling parameter γ was introduced [116, 117], where $J_{\parallel}/\gamma$ characterizes the interaction strength along the legs for the integrable spin ladder.

From the above analysis, when $H \leq H_{c1} = 8.6 \text{ T}$ the ground state is the product of rung singlets such that the magnetization $M^z = 0$. If $H_{c1} < H < H_{IP} = 9.42 \text{ T}$, the dressed energies $\epsilon^{(2)}$ and $\epsilon^{(3)}$ are both gapful, so that the magnetization is given by

$$M^z = \int_{-Q}^Q \rho^{(1)}(v) dv \quad (43)$$

where

$$\rho^{(1)}(v) = \frac{1}{2\pi} \frac{1}{v^2 + \frac{1}{4}} - \frac{1}{2\pi} \int_{-Q}^Q \frac{2}{1 + (v - k)^2} \rho^{(1)}(k) dk. \quad (44)$$

In the above equations Q denotes the Fermi boundary determined from

$$\epsilon^{(1)}(v) = -2\pi J_{\parallel} a_1(v) + J_{\perp} - \mu_B g H - \frac{1}{2\pi} \int_{-Q}^Q \frac{2}{1 + (v - k)^2} \epsilon^{(1)-}(k) dk. \quad (45)$$

In the region where the magnetic field is greater than 9.42 T but less than $H_{c2} = 10.2 \text{ T}$, the Fermi boundary is determined by

$$\epsilon^{(1)}(v) = -2\pi J_{\parallel} a_1(v) - J_{\perp} + \mu_B g H - \frac{1}{2\pi} \int_{-Q}^Q \frac{2}{1 + (v - k)^2} \epsilon^{(1)-}(k) dk \quad (46)$$

Figure 4. Comparison between theory and experiment for magnetization versus magnetic field H in units of saturation magnetization for the strong coupling ladder compound $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$ [42]. The theoretical curves are obtained from the integrable model with the values $J_\perp = 13.3$ K, $J_\parallel = 0.2875$ K and $g = 2.1$. The full curve is obtained from the TBA equations at zero temperature. For further comparison, the dashed curve is obtained using the HTE at $T = 0.4$ K, as outlined in section 5. The experimental magnetization at $T = 0.4$ K (diamonds) is shown for comparison. The discrepancy in the curves at $T = 0.4$ K is due to paramagnetic impurities, which result in nonzero magnetization in the singlet ground state. At the inflection point, $H = J_\perp/\mu_B g$, the magnetization is 0.5. Both the TBA and HTE curves indicate values of the critical fields in excellent agreement with the experimental results.

and the magnetization is

$$M^z = 1 - \int_{-Q}^Q \rho^{(1)}(v) dv. \quad (47)$$

The numerical solution of these equations gives a reasonable magnetization curve (see figure 4) which passes through an inflection point midway between H_{c1} and H_{c2} . The inflection point has a physical meaning in that the probabilities of the singlet $|1\rangle$ and the triplet state $|2\rangle$ in the ground state are equal. At zero temperature, in the strong coupling regime, the one point correlation function, $\langle S_j \cdot T_j \rangle = -\frac{3}{4}$, lies in a gapped singlet groundstate, which indicates an ordered dimer phase, while $\langle S_j \cdot T_j \rangle = \frac{1}{4}$ in the fully-polarized ferromagnetic phase. However, in the Luttinger liquid phase, $\langle S_j \cdot T_j \rangle = -\frac{3}{4} + M^z$. This indicates that the magnetic field increases the value of the one point correlation function.

3.4 Small Fermi boundary expansion method in the vicinity of the critical fields

It was shown [116, 117] that the magnetization in the vicinity of the critical fields H_{c1} and H_{c2} depends on the square root of the field, indicating a Pokrovsky-Talapov transition. An analytic expression for the field-dependent magnetization in the vicinity of the critical points H_{c1} and H_{c2} can be obtained by a small Q approximation. The lower left panel of figure 3 shows the dressed energies $\epsilon^{(k)}$, $k = 1, 2, 3$ in the vicinity of the critical point H_{c1} .

Performing a small Q approximation in (45) gives

$$\begin{aligned}\epsilon^{(1)}(v) &= -2\pi J_{\parallel} a_1(v) + J_{\perp} - \mu_B g H - \frac{1}{2\pi} \int_{-Q}^Q \frac{2}{1 + (v - k)^2} \epsilon^{(1)-}(k) dk \\ &\approx -\frac{4J_{\parallel}}{1 + 4v^2} + J_{\text{eff}} - \frac{2Q}{\pi} \frac{1}{1 + v^2} \epsilon^{(1)}(0)\end{aligned}\quad (48)$$

with $J_{\text{eff}} = J_{\perp} - \mu_B g H$. It follows that

$$\epsilon^{(1)}(0) \approx \frac{(J_{\text{eff}} - 4J_{\parallel})\pi}{\pi + 2Q} = -\frac{\mu_B g (H - H_{c1})\pi}{\pi + 2Q} \quad (49)$$

with $H_{c1} = (J_{\perp} - 4J_{\parallel})/(\mu_B g)$. The condition $\epsilon^{(1)}(Q) = 0$ then gives

$$Q \approx \sqrt{\frac{\mu_B g (H - H_{c1})}{16J_{\parallel} - 5\mu_B g (H - H_{c1})}}. \quad (50)$$

Similarly, equation (44) becomes

$$\rho^{(1)}(v) \approx \frac{1}{2\pi} \frac{1}{v^2 + 1/4} - \frac{4Q}{\pi(1 + v^2)} \rho^{(1)}(0) \quad (51)$$

with $\rho^{(1)}(0) = \frac{2}{\pi + 4Q}$. The magnetization for small Q can then be obtained as

$$M^z = \int_{-Q}^Q \rho^{(1)}(v) dv \approx \frac{4Q}{\pi} \left(1 - \frac{2Q}{\pi}\right). \quad (52)$$

It follows that the magnetization in the vicinity of H_{c1} has a square root field-dependent critical behaviour of the form

$$M^z \approx \frac{1}{\pi} \sqrt{\mu_B g (H - H_{c1})/J_{\parallel}}. \quad (53)$$

The thermodynamics may be calculated from the free energy (39) and (41). To demonstrate this, we look at the free energy in the vicinity of H_{c2} via the TBA equations (42). When $H > J_{\perp}/\mu_B g$, the lowest energy level $|2\rangle$ dominates other states as the magnetic field increases. The basis order is chosen to be $(|2\rangle, |1\rangle, |3\rangle, |4\rangle)$. In fact, a Luttinger liquid phase lies in the regime $H_{c1} < H < H_{c2}$, where the ground state can be described by an integrable XXZ model with an effective field $H - J_{\perp}/\mu_B g$, see (46). Similarly, in the vicinity of H_{c2} , from (46), we have

$$\epsilon^{(1)}(0) \approx -\frac{(J_{\text{eff}} + 4J_{\parallel})\pi}{\pi + 2Q} = -\frac{\mu_B g(H_{c2} - H)\pi}{\pi + 2Q} \quad (54)$$

$$Q \approx \sqrt{\frac{\mu_B g(H_{c2} - H)}{16J_{\parallel} - 5\mu_B g(H_{c2} - H)}} \quad (55)$$

with $H_{c2} = (J_{\perp} + 4J_{\parallel})/\mu_B g$. Here the Fermi boundary Q is very small for H near H_{c2} . Subsequently, the free energy can be derived from (41) as

$$\begin{aligned} F(0, H) &= -\mu_B g H - T \int_{-\infty}^{\infty} a_1(v) \ln(1 + e^{-\epsilon_1^{(1)}(v)/T}) dv \\ &= -\mu_B g H + \int_{-\infty}^{\infty} a_1(v) \epsilon_1^{(1)-}(v) dv \\ &= -\mu_B g H + \int_{-Q}^Q a_1(v) \epsilon_1^{(1)}(v) dv \\ &= -\mu_B g H + \int_{-Q}^Q a_1(v) \left[-2\pi J_{\parallel} a_1(v) + J'_{\text{eff}} - \frac{2Q\epsilon_1^{(1)}(0)}{\pi} \frac{1}{1+v^2} \right] dv \\ &= -\mu_B g H - \frac{4Q\mu_B g(H_{c2} - H)}{\pi} \left(1 + \frac{2Q}{\pi} \right). \end{aligned} \quad (56)$$

For very small Q the magnetization is given by

$$M^z \approx \frac{F(0, H_{c2}) - F(0, H)}{M_s(H_{c2} - H)} \quad (57)$$

with $M_s = \mu_B g$. Thus

$$M^z \approx 1 - \frac{1}{\pi} \sqrt{\mu_B g(H_{c2} - H)/J_{\parallel}}. \quad (58)$$

The results (53) and (58) demonstrate the square root critical behaviour.

They coincide with the numerical results, as applied to the strong coupling ladder compound $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$ in figure 4.

3.5 Wiener-Hopf method

The Wiener-Hopf technique has been widely used to solve functional equations which are obtained by Fourier transformation of certain integral equations [128, 124, 125, 175]. In this subsection we demonstrate how to analytically solve the TBA equations with a large Fermi surface.

The higher energy levels of the triplet states $|3\rangle$ and $|4\rangle$ are always suppressed in the ground state for strong rung coupling ($J_\perp > 4J_\parallel$). The spin waves are hard-core bosons with massless excitations. In the regime $H_{c1} < H < H_{c2}$, the ground state is that of the integrable XXZ chain with an effective field $H - J_\perp/\mu_B g$. This field triggers two pure states, namely $|0\rangle$ for $H < H_{c1}$ and $|2\rangle$ for $H > H_{c2}$, which effectively correspond to the states $|\downarrow\rangle$ and $|\uparrow\rangle$ of the XXZ model, respectively. The inflection point $H = J_\perp/\mu_B g$ may be considered as the $su(2)$ point because at this point $J_\perp$ is diminished by external fields. It reduces to the TBA equation without any chemical potential for XXX model where the ground state is the $su(2)$ Luttinger liquid. These two components are degenerate and fully fill the energy band $\epsilon^{(1)}$. All other bands are empty (as per the lower right panel of figure 3). When the magnetic field is greater than $J_\perp$, i.e., when $H > \frac{J_\perp}{\mu_B g}$, the Zeeman energy introduces a large Fermi surface of the dressed energy $\epsilon^{(1)}$ with regard to the basis order $(|2\rangle, |1\rangle, |3\rangle, |4\rangle)$. Logarithmic corrections are associated with the interference effects between the two Fermi boundaries.

The integral equations (45) and (46) exhibit a large Fermi boundary for H in the vicinity of $J_\perp/\mu_B g$ and can be solved by the Wiener-Hopf method. We thus consider the case of H in the vicinity of $J_\perp/\mu_B g$ such that the ground state is described by the $su(2)$ TBA equation with an effective field. With $J_{\text{eff}} = -J_\perp + \mu_B g H$, equation (46) can then be rewritten as

$$\epsilon^{(1)}(v) = -J_\parallel 2\pi a_1(v) + J_{\text{eff}} - (a_2 * \epsilon^{(1)-})(v). \quad (59)$$

Taking Fourier transforms, defined by $\tilde{f}(\omega) = \int_{-\infty}^{\infty} f(\lambda) e^{i\omega\lambda} d\lambda$, gives

$$\tilde{\epsilon}^{(1)}(\omega) = -J_\parallel 2\pi \frac{e^{-\frac{|\omega|}{2}}}{1 + e^{-|\omega|}} + \frac{1}{2} J_{\text{eff}} \delta(\omega) + \frac{e^{-|\omega|}}{1 + e^{-|\omega|}} \tilde{\epsilon}^{(1)+}(\omega). \quad (60)$$

Define the function $G(\lambda)$ by

$$G(\lambda) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{e^{-|\omega|/2}}{2 \cosh \frac{\omega}{2}} e^{-i\lambda\omega} d\omega.$$

Then the inverse Fourier transform indicates that the dressed energy satisfies a Wiener-Hopf type equation of the form

$$\epsilon^{(1)}(\lambda) = -J_{\parallel} \frac{\pi}{\cosh \pi \lambda} + \frac{1}{2} J_{\text{eff}} + \left(\int_{-\infty}^{-B} + \int_B^{\infty} \right) (G * \epsilon^{(1)})(k) dk. \quad (61)$$

Because J_{eff} is very small, the Fermi boundary is very large. Let $\lambda \rightarrow \lambda + B$ and $y(\lambda) = \epsilon^{(1)}(\lambda + B)$, then equation (61) becomes

$$\begin{aligned} y(\lambda) = & -J_{\parallel} \frac{\pi}{\cosh \pi(\lambda + B)} + \frac{1}{2} J_{\text{eff}} + \int_0^{\infty} G(\lambda + 2B - k) y(k) dk \\ & + \int_0^{\infty} G(\lambda - k) y(k) dk. \end{aligned} \quad (62)$$

Now $G(\lambda + 2B - k) \rightarrow e^{-B}$ as $B \gg 1$. The driving term can be expanded in powers of e^{-B} . We can thus take an expansion $y = y_1 + y_2 + y_3 + \dots$ with respect to the order of e^{-mB} , $m = 1, 2, \dots$. The leading term y_1 describes interference between the two Fermi points. The energy of the excitation is proportional to the momentum. Subsequently, we have

$$y_1(\lambda) = -J_{\parallel} 2\pi e^{-(\lambda+B)\pi} + \frac{1}{2} J_{\text{eff}} + \int_0^{\infty} G(\lambda - k) y_1(k) dk \quad (63)$$

$$y_2(\lambda) = \int_0^{\infty} G(\lambda - k) y_2(k) dk + \int_0^{\infty} G(\lambda + 2B - k) y_1(k) dk \quad (64)$$

$$y_3(\lambda) = \int_0^{\infty} G(\lambda - k) y_3(k) dk + \int_0^{\infty} G(\lambda + 2B - k) y_2(k) dk \quad (65)$$

and so on.

Each of these equations is of Wiener-Hopf type and can be solved in an analytic fashion. Here we content ourselves with the leading term, i.e., considering the leading pole in the decomposed functions. The remaining higher terms y_n can be obtained by iteration. Introduce the functions $y_{\pm}(\lambda)$ by

$$y_1^+(\lambda) = \begin{cases} y(\lambda), & \lambda > 0 \\ 0, & \lambda < 0, \end{cases} \quad y_1^-(\lambda) = \begin{cases} y(\lambda), & \lambda < 0 \\ 0, & \lambda > 0. \end{cases} \quad (66)$$

Taking the Fourier decomposition, we have $\tilde{y}_1(\omega) = \tilde{y}_1^+(\omega) + \tilde{y}_1^-(\omega)$, where $\tilde{y}_1^\pm(\omega)$ are analytic in the upper and lower halves of the complex plane, respectively. In order to solve the Wiener-Hopf equations, we need to find a decomposition of the kernel and the driving term in (63). To this end, we denote the driving term by

$$\phi(\lambda) = -J_{\parallel} 2\pi e^{-(\lambda+B)\pi} + \frac{1}{2} J_{\text{eff}} \quad (67)$$

and define Fourier transform for driving term

$$\begin{aligned} \phi_+(\lambda) &= \begin{cases} 0, & \lambda < 0 \\ \frac{1}{2\pi} \oint e^{-i\omega\lambda} \tilde{\phi}_+(\omega) d\omega = \phi(\lambda), & \lambda > 0 \end{cases} \\ \phi_-(\lambda) &= \begin{cases} 0, & \lambda > 0 \\ \frac{1}{2\pi} \oint e^{-i\omega\lambda} \tilde{\phi}_-(\omega) d\omega = \phi(\lambda), & \lambda < 0. \end{cases} \end{aligned}$$

Where the first (second) half-circle contour integral in the above equations is carried out in the lower (upper) half complex plane. The functions $\tilde{\phi}_\pm(\omega)$ are analytic in the upper (+) and lower (-) halves of the complex plane. Applying the forward Fourier transformations then gives

$$\frac{\tilde{y}_1^+(\omega)}{a_+(\omega)a_-(\omega)} + \tilde{y}_1^-(\omega) = \tilde{\phi}_+(\omega) + \tilde{\phi}_-(\omega) \quad (68)$$

where

$$a_+(\omega)a_-(\omega) = [1 - \tilde{G}(\omega)]^{-1} = \frac{e^{\frac{|\omega|}{2}}}{2 \cosh \frac{|\omega|}{2}}. \quad (69)$$

Explicitly,

$$a_+(\omega) = a_-(-\omega) = \sqrt{2\pi} \left(\frac{\eta - i\omega}{2\pi e} \right)^{-\frac{i\omega}{2\pi}} / \Gamma \left(\frac{1}{2} - \frac{i\omega}{2\pi} \right) \quad (70)$$

$$\phi_+(\omega) = i \left(\frac{J_{\text{eff}}}{2(\omega + i\epsilon)} - \frac{2J_{\parallel} e^{-B\pi}}{\omega + i\pi} \pi \right). \quad (71)$$

Here $\Gamma(z)$ is the gamma function. The common strip of analyticity for $a_\pm(\omega)$ is $\omega \in (-i\pi, i\pi)$.

In the above equations, $a_\pm(\omega)$ factorize the kernel and are analytic in the upper and lower halves of the complex plane, respectively. From equation (68),

we obtain

$$\frac{\tilde{y}_1^+(\omega)}{a_+(\omega)} - \tilde{\Phi}_+(\omega) = \tilde{\Phi}_-(\omega) + \phi_-(\omega)a_-(\omega) - \tilde{y}_1^-(\omega)a_-(\omega). \quad (72)$$

Here we have used the decomposition $\tilde{\phi}_+(\omega)a_-(\omega) = \tilde{\Phi}_+(\omega) - \tilde{\Phi}_-(\omega)$, where $\tilde{\Phi}_+$ is given by (the evaluation of $\tilde{\Phi}_-$ is not necessary in the following)

$$\tilde{\Phi}_+(\omega) = i \left(\frac{J_{\text{eff}} a_-(0)}{2(\omega + i\epsilon)} - \frac{2J_{\parallel} e^{-B\pi} a_-(-i\pi)}{\omega + i\pi} \right). \quad (73)$$

Owing to the analytic properties of both sides of (72), they should equal some entire function, since both sides tend to zero as $\omega \rightarrow \infty$. Here this entire function turns out to be zero.

At the Fermi point

$$y_1(0) \equiv \epsilon^{(1)}(B) = \frac{1}{2\pi} \int_0^\infty \tilde{y}_1(\omega) d\omega = 0 \quad (74)$$

where $\tilde{y}_1(\omega)$ is analytic in the upper half of the complex plane. Therefore $\lim_{|\omega| \rightarrow \infty} \omega \tilde{y}_1(\omega) = 0$ holds, which yields

$$e^{-B\pi} = \frac{J_{\text{eff}} a_-(0)}{4\pi J_{\parallel} a_-(-i\pi)}. \quad (75)$$

We see that the Fermi boundary decreases monotonically with increasing magnetic field. Subsequently, we have

$$\tilde{y}_1^+(\omega) = \tilde{\Phi}_+(\omega)a_+(\omega) = i \frac{1}{2} J_{\text{eff}} \left(\frac{1}{\omega + i\epsilon} - \frac{1}{\omega + i\pi} \right) a_-(0)a_+(\omega). \quad (76)$$

Similarly, $\tilde{y}_-(\omega)$ can be obtained from the right hand side of equation (72). Nevertheless, we only need $\tilde{y}_+(\omega)$ for calculating the free energy. From equation (41) we then have

$$\begin{aligned} F(0, H) = & -\mu_B g H - T \int_{-\infty}^{\infty} a_1(v) \ln(1 + e^{-\epsilon_1^{(1)}(v)/T}) dv \\ & + \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-|\omega|/2} [\tilde{G}(\omega) - 1] \epsilon^{(1)+}(\omega) d\omega \end{aligned}$$

$$\begin{aligned}
&= F(0,0) + \frac{1}{2}(J_{\perp} - \mu_B g H) - \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \frac{\tilde{\epsilon}^{(1)+}(\omega)}{2 \cosh \frac{\omega}{2}} \\
&= F(0,0) + \frac{1}{2}(J_{\perp} - \mu_B g H) - \left(\frac{J_{\text{eff}}}{4\pi} \right)^2 \frac{a_{-}(0)a_{+}(0)}{J_{\parallel}}. \quad (77)
\end{aligned}$$

Here finally $a_{-}(0)a_{+}(0) = 2$. The zero field free energy $F(0,0) = -J_{\parallel}(\Psi(1) - \Psi(\frac{1}{2}))$, where $\Psi(a)$ is the digamma function. It follows that the susceptibility behaves like $\chi \approx \frac{(\mu_B g)^2}{4\pi^2 J_{\parallel}}$, indicating $su(2)$ symmetry at this point as the field diminishes the rung interaction. This susceptibility is consistent with that of the isotropic Heisenberg XXX chain, where $J_{\parallel} = \frac{1}{4}$ and $h = H/2$ [5]. It is seen that at the inflection point the model can be mapped onto the $su(2)$ isotropic Heisenberg chain with zero field.

4 The quantum transfer matrix and nonlinear integral equation approach

In this section we review the recently developed high-temperature expansion (HTE) formalism for integrable models, including the quantum transfer matrix (QTM) approach and the derivation of the temperature-dependant free energy via nonlinear integral equations with only a finite number of unknown functions. This paves the way for the application of this approach to the integrable spin ladder models and to the physical description of the strong coupling ladder compounds. The final results can be applied without any knowledge of the QTM and HTE. This can be done by inserting the chemical potential terms μ_i of a given model into the free energy expansion (128), which gives instant access to finite temperature physical properties, as shown for a number of ladder compounds in section 5.

The QTM relates a d -dimensional quantum system at finite temperature to a $(d+1)$ -dimensional classical system on an inhomogeneous lattice via the so-called Trotter-Suzuki mapping [135, 136, 137, 138, 139, 140]. In one-dimension, it involves a general relation between the transfer matrix $t(u) = e^{i\hat{P} + u\mathcal{H} + O(u^2)}$ and the Hamiltonian $\mathcal{H}$ of a quantum system, where $\hat{P}$ denotes the momentum operator. One also introduces an auxiliary transfer matrix $\tilde{t}(u)$ which is adjoint to $t(u)$ such that $\tilde{t}(u) = e^{-i\hat{P} + u\mathcal{H} + O(u^2)}$. In this way the partition function Z_L of the one-dimensional system at finite temperature is mapped to that of a staggered two-dimensional vertex model, with $Z_L = \text{tr} e^{-\beta\mathcal{H}} = \lim_{N \rightarrow \infty} Z_{L,N}$, where $\beta = 1/T$ and $Z_{L,N} = \text{tr} [t(-\beta/N)\tilde{t}(-\beta/N)]^{N/2}$. The trace tr is carried out on the quantum space, as opposed to the auxiliary space. In the following we show explicitly that the partition function of the one-dimensional quantum

system is given by $Z_{L,N} = \text{tr} [t_{\text{QTM}}(0)]^L$, where the QTM $t_{\text{QTM}}(u)$ is defined on the columns of the two-dimensional lattice. The QTM forms a commuting family, i.e., $[t_{\text{QTM}}(u), t_{\text{QTM}}(v)] = 0$, by the virtue of the Yang-Baxter equation. Thus the problem of describing the thermodynamics of one-dimensional quantum systems reduces to finding the largest eigenvalue of the QTM of a finite two-dimensional classical lattice model. In particular, the free energy per unit length is given by

$$f = - \lim_{L \rightarrow \infty} \frac{1}{L\beta} \ln Z_{L,N} = - \frac{1}{\beta} \ln \Lambda_{\max}(0).$$

In general the next leading eigenvalues of the QTM give the exponential correlation length ξ of the equal time correlations.

4.1 Preliminaries

Our starting point is the $su(r+1)$ Uimin-Lai-Sutherland, or permutator, model [9,10,11], for which one can define the QTM [135,136,137,138,139,140] and the T -system [144,145,146]. A description of the QTM approach for the Uimin-Lai-Sutherland model can be found in [141,142]. This involves working with the two-dimensional classical counterpart of the Uimin-Lai-Sutherland model, which is a rational limit of the Perk-Schultz model [14].

Let $\{|1\rangle, |2\rangle, \dots, |r+1\rangle\}$ be an orthonormal basis of an $r+1$ dimensional fundamental representation V of $su(r+1)$, and $\{\langle 1|, \langle 2|, \dots, \langle r+1|\}$ be its dual, with $\langle a|b\rangle = \delta_{ab}$. The R -matrix is given by [14]

$$R(v)|a\rangle \otimes |b\rangle = \sum_{a'=1}^{r+1} \sum_{b'=1}^{r+1} |a'\rangle \otimes |b'\rangle R_{ab}^{a'b'}(v) \quad (78)$$

with the matrix element (see figure 5)

$$R_{ab}^{a'b'}(v) = \langle a'| \otimes \langle b'| R(v) |a\rangle \otimes |b\rangle = v \delta_{aa'} \delta_{bb'} + \delta_{a'b} \delta_{ab'} \quad (79)$$

where $v \in \mathbb{C}$ and $a, b, a', b' \in \{1, 2, \dots, r+1\}$.

Further let $V_1, V_2, \dots, V_L, \hat{V}_1, \hat{V}_2, \dots, \hat{V}_N$ be copies of V , i.e., $V_j = \hat{V}_j = V$, where $L, N/2 \in \mathbb{Z}_{\geq 1}$. The row-to-row transfer matrix with periodic boundary conditions, which acts on the quantum space $V_1 \otimes V_2 \otimes \dots \otimes V_L$, is defined as

$$t(v) = \text{tr}_{\hat{V}_{2k}} (R_{2k,L}(v) \cdots R_{2k,2}(v) R_{2k,1}(v)), \quad k = 1, 2, \dots, N/2 \quad (80)$$

Figure 5. The Boltzmann weights $R_{a_2, b_2}^{a_1, b_1}(v)$ of the vertex model.Figure 6. The transfer matrix $t(v)_{\{\beta_1, \dots, \beta_L\}}^{\{\alpha_1, \dots, \alpha_L\}}$. The dots denote summations in definition (82).

where $R_{ab}(v)$ acts on $\hat{V}_1 \otimes \hat{V}_2 \otimes \dots \otimes \hat{V}_N \otimes V_1 \otimes V_2 \otimes \dots \otimes V_L$ such that

$$\begin{aligned}
 & R_{ab}(v) |\nu_1\rangle \otimes \dots \otimes |\nu_a\rangle \otimes \dots \otimes |\nu_N\rangle \otimes |\alpha_1\rangle \otimes \dots \otimes |\alpha_b\rangle \otimes \dots \otimes |\alpha_L\rangle \\
 &= \sum_{\xi_a=1}^{r+1} \sum_{\eta_b=1}^{r+1} |\nu_1\rangle \otimes \dots \otimes |\xi_a\rangle \otimes \dots \otimes |\nu_N\rangle \otimes |\alpha_1\rangle \otimes \dots \\
 & \quad \dots \otimes |\eta_b\rangle \otimes \dots \otimes |\alpha_L\rangle R_{\nu_a, \alpha_b}^{\xi_a, \eta_b}(v). \tag{81}
 \end{aligned}$$

Here $\nu_j, \alpha_j \in \{1, 2, \dots, r+1\}$ and the matrix element is defined as (see figure 6)

$$t(v)_{\{\beta_1, \dots, \beta_L\}}^{\{\alpha_1, \dots, \alpha_L\}} = \langle \alpha_1 | \otimes \langle \alpha_2 | \otimes \dots \otimes \langle \alpha_L | t(v) | \beta_1 \rangle \otimes | \beta_2 \rangle \otimes \dots \otimes | \beta_L \rangle \tag{82}$$

where $\alpha_j, \beta_j \in \{1, 2, \dots, r+1\}$.

The Hamiltonian $\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_{\text{ch}}$ of the model, which acts on $V_1 \otimes V_2 \otimes \dots \otimes V_L$, consists of two parts. The first part $\mathcal{H}_0$ characterizing the intrachain

interaction is given by (see also section 2)

$$\mathcal{H}_0 = J_{\parallel} \frac{d}{dv} \ln t(v)|_{v=0}. \quad (83)$$

The second part is of the form $\mathcal{H}_{\text{ch}} = \sum_{j=1}^L \mathcal{H}_j$, where $\mathcal{H}_j$ acts non-trivially on the j th site of the quantum space V_j . It contains the chemical potential terms which include the rung interaction and magnetic field. Explicitly,

$$\mathcal{H}_{\text{ch}} = J_{\perp} \sum_{j=1}^L \vec{S}_j \cdot \vec{T}_j - \mu_B g H \sum_{j=1}^L (S_j^z + T_j^z) \quad (84)$$

for Hamiltonian (3). As discussed in section 2.2, the chemical potential terms can be diagonalised in a suitable eigenbasis. The chemical potentials μ_{α} are given by

$$\langle \alpha_1 | \otimes \cdots \otimes \langle \alpha_L | \mathcal{H}_j | \beta_1 \rangle \otimes \cdots \otimes | \beta_L \rangle = \mu_{\alpha_j} \delta_{\alpha_1 \beta_1} \cdots \delta_{\alpha_L \beta_L} \quad (85)$$

for $j = 1, \dots, L$. For example, for Hamiltonian (3), the eigenbasis can be chosen as given in equation (5), for which the chemical potentials are given by

$$\mu_1 = -J_{\perp}, \quad \mu_2 = -\mu_B g H, \quad \mu_3 = 0, \quad \mu_4 = \mu_B g H. \quad (86)$$

We also define an auxiliary transfer matrix with periodic boundary conditions, which acts on $V_1 \otimes V_2 \otimes \cdots \otimes V_L$ as

$$\tilde{t}(v) = \text{tr}_{\hat{V}_{2k-1}} (\tilde{R}_{2k-1,L}(v) \cdots \tilde{R}_{2k-1,2}(v) \tilde{R}_{2k-1,1}(v)), \quad k = 1, 2, \dots, \frac{N}{2}. \quad (87)$$

Here $\tilde{R}(v)$ is essentially a 90 degree counterclockwise rotation of $R(v)$, whose components are given by $\tilde{R}_{a_2, b_2}^{a_1, b_1}(v) = R_{b_2, a_1}^{b_1, a_2}(v)$ (see figure 7). $\tilde{R}_{ab}(v)$ acts on the space $\hat{V}_1 \otimes \hat{V}_2 \otimes \cdots \otimes \hat{V}_N \otimes V_1 \otimes V_2 \otimes \cdots \otimes V_L$ such that

$$\begin{aligned} & \tilde{R}_{ab}(v) |\nu_1\rangle \otimes \cdots \otimes |\nu_a\rangle \otimes \cdots \otimes |\nu_N\rangle \otimes |\alpha_1\rangle \otimes \cdots \otimes |\alpha_b\rangle \otimes \cdots \otimes |\alpha_L\rangle \\ &= \sum_{\xi_a=1}^{r+1} \sum_{\eta_b=1}^{r+1} |\nu_1\rangle \otimes \cdots \otimes |\xi_a\rangle \otimes \cdots \\ & \quad \otimes |\nu_N\rangle \otimes |\alpha_1\rangle \otimes \cdots \otimes |\eta_b\rangle \otimes \cdots \otimes |\alpha_L\rangle R_{\alpha_b, \xi_a}^{\eta_b, \nu_a}(v) \end{aligned} \quad (88)$$

Figure 7. 90 degree rotation $\tilde{R}_{a_2, b_2}^{a_1, b_1}(v) = R_{b_2, a_1}^{b_1, a_2}(v)$ of $R(v)$.

Figure 8. The transfer matrix $\tilde{t}(v)_{\{\beta_1, \dots, \beta_L\}}^{\{\alpha_1, \dots, \alpha_L\}}$ defined in (87). Summations are taken at the dots.

where $\nu_j, \alpha_j \in \{1, 2, \dots, r+1\}$. The matrix element is defined as (see figure 8)

$$\tilde{t}(v)_{\{\beta_1, \dots, \beta_L\}}^{\{\alpha_1, \dots, \alpha_L\}} = \langle \alpha_1 | \otimes \dots \otimes \langle \alpha_L | \tilde{t}(v) | \beta_1 \rangle \otimes \dots \otimes | \beta_L \rangle \quad (89)$$

where $\alpha_j, \beta_j \in \{1, 2, \dots, r+1\}$.

The logarithmic derivative of (87) also reproduces $\mathcal{H}_0$. Explicitly,

$$\begin{aligned} t(v) &= t(0) \{1 + \mathcal{H}_0 v / J_{\parallel} + \mathcal{O}(v^2)\} \\ \tilde{t}(v) &= \tilde{t}(0) \{1 + \mathcal{H}_0 v / J_{\parallel} + \mathcal{O}(v^2)\}. \end{aligned} \quad (90)$$

As $t(0)$ and $\tilde{t}(0)$ are, respectively, left and right translation operators, then

$$t(v)\tilde{t}(v) = 1 + 2\mathcal{H}_0 v / J_{\parallel} + \mathcal{O}(v^2). \quad (91)$$

4.2 Quantum Transfer Matrix method

The partition function Z_L can now be written in terms of the transfer matrices as

$$\begin{aligned}
Z_L &= \text{tr}_{V_1 \otimes \dots \otimes V_L} e^{-\beta \mathcal{H}} = \text{tr}_{V_1 \otimes \dots \otimes V_L} e^{-\beta \mathcal{H}_{\text{ch}}} e^{-\beta \mathcal{H}_0} \\
&= \lim_{N \rightarrow \infty} \text{tr}_{V_1 \otimes \dots \otimes V_L} e^{-\beta \mathcal{H}_{\text{ch}}} \left(1 - \frac{2\beta \mathcal{H}_0}{N} \right)^{\frac{N}{2}} \\
&= \lim_{N \rightarrow \infty} \text{tr}_{V_1 \otimes \dots \otimes V_L} e^{-\beta \mathcal{H}_{\text{ch}}} (t(u_N) \tilde{t}(u_N))^{\frac{N}{2}} \quad (92)
\end{aligned}$$

where N is the Trotter number, defined by $u_N = -J_{\parallel} \beta / N$, with $\beta = 1/T$ the inverse temperature. Here we have set the Boltzmann constant to be unity and have used (91), along with commutativity of $\mathcal{H}_0$ and $\mathcal{H}_{\text{ch}}$ and the formula $\lim_{N \rightarrow \infty} \text{tr} (1 - \frac{A}{N})^N = \text{tr} e^{-A}$ for a suitable operator A . The free energy per site is

$$\begin{aligned}
f &= - \lim_{L \rightarrow \infty} \frac{1}{L\beta} \ln Z_L \\
&= - \lim_{L \rightarrow \infty} \lim_{N \rightarrow \infty} \frac{1}{\beta L} \ln \text{tr}_{V_1 \otimes \dots \otimes V_L} e^{-\beta \mathcal{H}_{\text{ch}}} (t(u_N) \tilde{t}(u_N))^{\frac{N}{2}}. \quad (93)
\end{aligned}$$

In general, the eigenvalues of $t(u_N) \tilde{t}(u_N)$ may be infinitely degenerate in the Trotter limit $N \rightarrow \infty$ ($u_N \rightarrow 0$) and taking the trace in (93) is not a trivial operation. To overcome this difficulty, we define an inhomogeneous transfer matrix – the QTM – with periodic boundary conditions,

$$\begin{aligned}
t_{\text{QTM}}(v) &= \text{tr}_{V_j} e^{-\beta \mathcal{H}_j} R_{N,j}(u_N + iv) \tilde{R}_{N-1,j}(u_N - iv) \dots \\
&\quad R_{4,j}(u_N + iv) \tilde{R}_{3,j}(u_N - iv) R_{2,j}(u_N + iv) \tilde{R}_{1,j}(u_N - iv) \quad (94)
\end{aligned}$$

which acts on $\hat{V}_1 \otimes \hat{V}_2 \otimes \dots \otimes \hat{V}_N$. The matrix element of the QTM is defined as

$$t_{\text{QTM}}(v)_{\{\beta_1, \dots, \beta_N\}}^{\{\alpha_1, \dots, \alpha_N\}} = \langle \alpha_1 | \otimes \dots \otimes \langle \alpha_N | t_{\text{QTM}}(v) | \beta_1 \rangle \otimes \dots \otimes | \beta_N \rangle$$

where $\alpha_j, \beta_j \in \{1, 2, \dots, r+1\}$. Explicitly, it may be written as (see figure 9)

$$t_{\text{QTM}}(v)_{\{b_1, \dots, b_N\}}^{\{a_1, \dots, a_N\}} =$$

Figure 9. The quantum transfer matrix $t_{\text{QTM}}^j(v)_{\{b_1, \dots, b_N\}}^{\{a_1, \dots, a_N\}}$. The dots denote summations in definition (95). The large dot stands for $e^{-\beta \mathcal{H}_j}$, $j \in \{1, 2, \dots, L\}$.

$$\sum_{\{\nu_k\}} e^{-\frac{\mu \nu_1}{T}} \prod_{k=1}^{N/2} R_{b_{2k}, \nu_{2k}}^{a_{2k}, \nu_{2k+1}}(u_N + iv) \tilde{R}_{b_{2k-1}, \nu_{2k-1}}^{a_{2k-1}, \nu_{2k}}(u_N - iv) \quad (95)$$

where $\nu_{N+1} = \nu_1$ and $\nu_k \in \{1, 2, \dots, r+1\}$. The QTM is connected to (see also figure 10)

$$\begin{aligned} & \text{tr}_{V_1 \otimes \dots \otimes V_L} e^{-\beta \mathcal{H}_{\text{ch}}} (t(u_N) \tilde{t}(u_N))^{\frac{N}{2}} \\ &= \text{tr}_{V_1 \otimes \dots \otimes V_L} e^{-\sum_{j=1}^L \beta \mathcal{H}_j} \prod_{k=1}^{\overleftarrow{N/2}} \text{tr}_{\hat{V}_{2k-1} \otimes \hat{V}_{2k}} \{ (R_{2k,L}(u_N) \cdots R_{2k,2}(u_N) R_{2k,1}(u_N)) \\ & \quad \times (\tilde{R}_{2k-1,L}(u_N) \cdots \tilde{R}_{2k-1,2}(u_N) \tilde{R}_{2k-1,1}(u_N)) \} \end{aligned}$$

Figure 10. The QTM lattice structure. Summations are taken at dotted points. Large dots stand for $e^{-\beta \mathcal{H}_j}$, $j \in \{1, 2, \dots, L\}$. The values $u = u_N$ and $v = 0$ correspond to equation (96). Horizontal lines with $u + iv$ correspond to $t(v)$ while horizontal lines with $u - iv$ correspond to $\tilde{t}(v)$. The vertical lines correspond to $t_{\text{QTM}}(v)$.

$$\begin{aligned}
&= \text{tr}_{V_1 \otimes \dots \otimes V_L} e^{-\sum_{j=1}^L \beta \mathcal{H}_j} \prod_{k=1}^{\overleftarrow{N/2}} \text{tr}_{\hat{V}_{2k-1} \otimes \hat{V}_{2k}} \{ (R_{2k,L}(u_N) \tilde{R}_{2k-1,L}(u_N)) \dots \\
&\quad \times (R_{2k,2}(u_N) \tilde{R}_{2k-1,2}(u_N)) (R_{2k,1}(u_N) \tilde{R}_{2k-1,1}(u_N)) \} \\
&= \text{tr}_{\hat{V}_1 \otimes \dots \otimes \hat{V}_N} \prod_{j=1}^{\overleftarrow{L}} \text{tr}_{V_j} e^{-\beta \mathcal{H}_j} \prod_{k=1}^{\overleftarrow{N/2}} (R_{2k,j}(u_N) \tilde{R}_{2k-1,j}(u_N)) \\
&= \text{tr}_{\hat{V}_1 \otimes \dots \otimes \hat{V}_N} (t_{\text{QTM}}(0))^L. \tag{96}
\end{aligned}$$

Here the ordered product is defined by

$$\prod_{j=1}^{\overleftarrow{L}} A(j) = A(L) \cdots A(2)A(1)$$

for any indexed operator $\{A(j)\}$.

Let $\Lambda_1, \Lambda_2, \dots, \Lambda_{(r+1)^N}$ be all eigenvalues of $t_{\text{QTM}}(0)$ such that $\Lambda_1 \geq \Lambda_2 \geq \dots \geq \Lambda_{(r+1)^N}$. Then the free energy per site (93) is

$$f = - \lim_{L \rightarrow \infty} \lim_{N \rightarrow \infty} \frac{1}{\beta L} \ln \Lambda_1^L \left\{ 1 + \left(\frac{\Lambda_2}{\Lambda_1} \right)^L + \left(\frac{\Lambda_3}{\Lambda_1} \right)^L + \dots + \left(\frac{\Lambda_{(r+1)^N}}{\Lambda_1} \right)^L \right\}. \quad (97)$$

It is assumed that there is a finite gap between the largest and the second largest eigenvalues, Λ_1 and Λ_2 , of $t_{\text{QTM}}(0)$, at least when N is a finite number. This gap is expected to still exist in the Trotter limit if $T > 0$. Moreover, $\Lambda_1, \Lambda_2, \dots, \Lambda_{(r+1)^N}$ do not depend on L . Thus if we exchange [135, 136, 138] the order of the two limits $L \rightarrow \infty$ and $N \rightarrow \infty$ in (97), the free energy per site can be expressed in terms of only the largest eigenvalue Λ_1 of the QTM (94) at $v = 0$. Namely,

$$f = -T \lim_{N \rightarrow \infty} \log \Lambda_1 \quad (98)$$

a remarkably simple result.

Now the eigenvalue [142, 141, 176] $T_1^{(1)}(v)$ of the QTM (94) derived by the Bethe Ansatz is

$$T_1^{(1)}(v) = \sum_{d=1}^{r+1} z(d; v). \quad (99)$$

The functions $\{z(d; v)\}$ are defined as

$$z(a; v) = \psi_a(v) \frac{Q_{a-1}(v - \frac{1}{2}i(a+1))Q_a(v - \frac{1}{2}i(a-2))}{Q_{a-1}(v - \frac{1}{2}i(a-1))Q_a(v - \frac{1}{2}ia)} \quad (100)$$

for $a \in \{1, 2, \dots, r+1\}$, with

$$Q_a(v) = \prod_{k=1}^{M_a} (v - v_k^{(a)})$$

where $M_a \in \mathbb{Z}_{\geq 0}$ and $Q_0(v) = Q_{r+1}(v) = 1$. The vacuum parts $\psi_a(v)$ appearing in (100) are given by

$$\psi_a(v) = e^{-\mu_a/T} \phi_+(v + i\delta_{a,r+1}) \phi_-(v - i\delta_{a,1}) \quad (101)$$

for $a \in \{1, 2, \dots, r+1\}$ and $\phi_{\pm}(v) = (v \pm i u_N)^{N/2}$. The complex numbers $v_k^{(a)}$ satisfy the Bethe equation

$$\frac{\psi_a(v_k^{(a)} + \frac{1}{2}i a)}{\psi_{a+1}(v_k^{(a)} + \frac{1}{2}i a)} = -\frac{Q_{a-1}(v_k^{(a)} + \frac{1}{2}i)Q_a(v_k^{(a)} - i)Q_{a+1}(v_k^{(a)} + \frac{1}{2}i)}{Q_{a-1}(v_k^{(a)} - \frac{1}{2}i)Q_a(v_k^{(a)} + i)Q_{a+1}(v_k^{(a)} - \frac{1}{2}i)} \quad (102)$$

for $k \in \{1, 2, \dots, M_a\}$ and $a \in \{1, 2, \dots, r\}$.

All of the above is for general r . Specializing to the $su(4)$ ($r = 3$) case of relevance to the integrable ladder model (3), with chemical potential terms (86), we have

$$\begin{aligned} \frac{\phi_-(v_k^{(1)} - \frac{1}{2}i)}{\phi_-(v_k^{(1)} + \frac{1}{2}i)} &= -e^{\frac{\mu_1 - \mu_2}{T}} \frac{Q_1(v_k^{(1)} - i)Q_2(v_k^{(1)} + \frac{1}{2}i)}{Q_1(v_k^{(1)} + i)Q_2(v_k^{(1)} - \frac{1}{2}i)} \\ 1 &= -e^{\frac{\mu_2 - \mu_3}{T}} \frac{Q_1(v_k^{(2)} + \frac{1}{2}i)Q_2(v_k^{(2)} - i)Q_3(v_k^{(2)} + \frac{1}{2}i)}{Q_1(v_k^{(2)} - \frac{1}{2}i)Q_2(v_k^{(2)} + i)Q_3(v_k^{(2)} - \frac{1}{2}i)} \\ \frac{\phi_+(v_k^{(3)} + \frac{3}{2}i)}{\phi_+(v_k^{(3)} + \frac{5}{2}i)} &= -e^{\frac{\mu_3 - \mu_4}{T}} \frac{Q_2(v_k^{(3)} + \frac{1}{2}i)Q_3(v_k^{(3)} - i)}{Q_2(v_k^{(3)} - \frac{1}{2}i)Q_3(v_k^{(3)} + i)}. \end{aligned} \quad (103)$$

In the first line, $k \in \{1, 2, \dots, M_1\}$, in the second, $k \in \{1, 2, \dots, M_2\}$, and in the third $k \in \{1, 2, \dots, M_3\}$.

4.3 T -system

The next step is to introduce an auxiliary function $T_m^{(a)}(v)$, whose origin is related to a fusion hierarchy [177] of the QTM (cf. the Bazhanov-Reshetikhin

formula in [178]),

$$T_m^{(a)}(v) = \sum_{\{d_{j,k}\}} \prod_{j=1}^a \prod_{k=1}^m z(d_{j,k}; v - \frac{1}{2}i(a - m - 2j + 2k)) \quad (104)$$

where the summation is taken over $d_{j,k} \in \{1, 2, \dots, r+1\}$ such that $d_{j,k} \prec d_{j+1,k}$ and $d_{j,k} \preceq d_{j,k+1}$ ($1 \prec 2 \prec \dots \prec r+1$), with $m \in \mathbb{Z}_{\geq 1}$ and $a \in \{1, 2, \dots, r\}$. This general function $T_m^{(a)}(v)$ contains the eigenvalue $T_1^{(1)}(v)$ in (99) as a special case, namely $(a, m) = (1, 1)$. The poles of $T_m^{(a)}(v)$ are spurious due to the Bethe equations (102). The relation (104) can be interpreted as Young tableaux with spectral parameter v if we set $z(a; v) = \boxed{a; v}$.

For example, for the $su(4)$ case ($r = 3$), we have

$$T_1^{(1)}(u) = \boxed{1; v} + \boxed{2; v} + \boxed{3; v} + \boxed{4; v} \quad (105)$$

$$\begin{aligned} T_1^{(2)}(u) = & \frac{\boxed{1; v - \frac{1}{2}i}}{\boxed{2; v + \frac{1}{2}i}} + \frac{\boxed{1; v - \frac{1}{2}i}}{\boxed{3; v + \frac{1}{2}i}} + \frac{\boxed{1; v - \frac{1}{2}i}}{\boxed{4; v + \frac{1}{2}i}} + \frac{\boxed{2; v - \frac{1}{2}i}}{\boxed{3; v + \frac{1}{2}i}} + \frac{\boxed{2; v - \frac{1}{2}i}}{\boxed{4; v + \frac{1}{2}i}} \\ & + \frac{\boxed{3; v - \frac{1}{2}i}}{\boxed{4; v + \frac{1}{2}i}} \end{aligned} \quad (106)$$

$$\begin{aligned} T_2^{(1)}(u) = & \boxed{1; v + \frac{1}{2}i} \boxed{1; v - \frac{1}{2}i} + \boxed{1; v + \frac{1}{2}i} \boxed{2; v - \frac{1}{2}i} + \boxed{1; v + \frac{1}{2}i} \boxed{3; v - \frac{1}{2}i} \\ & + \boxed{1; v + \frac{1}{2}i} \boxed{4; v - \frac{1}{2}i} + \boxed{2; v + \frac{1}{2}i} \boxed{2; v - \frac{1}{2}i} + \boxed{2; v + \frac{1}{2}i} \boxed{3; v - \frac{1}{2}i} \\ & + \boxed{2; v + \frac{1}{2}i} \boxed{4; v - \frac{1}{2}i} + \boxed{3; v + \frac{1}{2}i} \boxed{3; v - \frac{1}{2}i} + \boxed{3; v + \frac{1}{2}i} \boxed{4; v - \frac{1}{2}i} \\ & + \boxed{4; v + \frac{1}{2}i} \boxed{4; v - \frac{1}{2}i} \end{aligned} \quad (107)$$

Here we have used the notation

$$\begin{aligned} z(d_{1,1}; v - \frac{1}{2}i) z(d_{2,1}; v + \frac{1}{2}i) &= \frac{\boxed{d_{1,1}; v - \frac{1}{2}i}}{\boxed{d_{2,1}; v + \frac{1}{2}i}} \\ z(d_{1,1}; v + \frac{1}{2}i) z(d_{1,2}; v - \frac{1}{2}i) &= \boxed{d_{1,1}; v + \frac{1}{2}i} \boxed{d_{1,2}; v - \frac{1}{2}i} \end{aligned}$$

In this sense, relation (104) represents the character of the m -th symmetric and the a -th anti-symmetric tensor representation of $su(r+1)$ with spectral parameter. For $a \in \{1, 2, \dots, r\}$ and $m \in \mathbb{Z}_{\geq 1}$, it may be normalised as

$\tilde{T}_m^{(a)}(v) = T_m^{(a)}(v)/\tilde{\mathcal{N}}_m^{(a)}(v)$, where

$$\begin{aligned} \tilde{\mathcal{N}}_m^{(a)}(v) &= \frac{\phi_-(v - \frac{1}{2}\mathbf{i}(a+m))\phi_+(v + \frac{1}{2}\mathbf{i}(a+m))}{\phi_-(v - \frac{1}{2}\mathbf{i}(a-m))\phi_+(v + \frac{1}{2}\mathbf{i}(a-m))} \\ &\times \prod_{j=1}^a \prod_{k=1}^m \phi_-(v - \frac{1}{2}\mathbf{i}(a-m-2j+2k))\phi_+(v - \frac{1}{2}\mathbf{i}(a-m-2j+2k)). \end{aligned} \quad (108)$$

One can show that $\tilde{T}_m^{(a)}(v)$ satisfies the functional relation

$$\tilde{T}_m^{(a)}(v + \frac{1}{2}\mathbf{i})\tilde{T}_m^{(a)}(v - \frac{1}{2}\mathbf{i}) = \tilde{T}_{m+1}^{(a)}(v)\tilde{T}_{m-1}^{(a)}(v) + \tilde{T}_m^{(a-1)}(v)\tilde{T}_m^{(a+1)}(v) \quad (109)$$

which is called the T -system [144,145,146]. Here $a \in \{1, 2, \dots, r\}$ and $m \in \mathbb{Z}_{\geq 1}$, with

$$\begin{aligned} \tilde{T}_0^{(a)}(v) &= 1, \quad \text{for } a \in \mathbb{Z}_{\geq 1} \\ \tilde{T}_m^{(0)}(v) &= \frac{\phi_-(v + \frac{1}{2}\mathbf{i}m)\phi_+(v - \frac{1}{2}\mathbf{i}m)}{\phi_-(v - \frac{1}{2}\mathbf{i}m)\phi_+(v + \frac{1}{2}\mathbf{i}m)}, \quad \text{for } m \in \mathbb{Z}_{\geq 1} \\ \tilde{T}_m^{(r+1)}(v) &= e^{\frac{-m(\mu_1+\mu_2+\dots+\mu_{r+1})}{T}} \quad \text{for } m \in \mathbb{Z}_{\geq 1}. \end{aligned} \quad (110)$$

It can be verified, for example, that (105)-(107) satisfy the T -system (109)

$$\begin{aligned} T_1^{(1)}(v + \frac{1}{2}\mathbf{i})T_1^{(1)}(v - \frac{1}{2}\mathbf{i}) &= \sum_{a=1}^4 \sum_{b=1}^4 \boxed{a; v + \frac{1}{2}\mathbf{i} | b; v - \frac{1}{2}\mathbf{i}} \\ &= \sum_{a \leq b} \boxed{a; v + \frac{1}{2}\mathbf{i} | b; v - \frac{1}{2}\mathbf{i}} + \sum_{a > b} \boxed{a; v + \frac{1}{2}\mathbf{i} | b; v - \frac{1}{2}\mathbf{i}} \\ &= \sum_{a \leq b} \boxed{a; v + \frac{1}{2}\mathbf{i} | b; v - \frac{1}{2}\mathbf{i}} + \sum_{a > b} \boxed{\frac{b; v - \frac{1}{2}\mathbf{i}}{a; v + \frac{1}{2}\mathbf{i}}} \\ &= T_2^{(1)}(v) + T_1^{(2)}(v). \end{aligned} \quad (111)$$

Then taking note of the relations

$$\mathcal{N}_1^{(1)}(v + \frac{1}{2}\mathbf{i})\mathcal{N}_1^{(1)}(v - \frac{1}{2}\mathbf{i}) = \mathcal{N}_2^{(1)}(v) = \mathcal{N}_1^{(2)}(v)/\tilde{T}_1^{(0)}(v) \quad (112)$$

gives the desired result

$$\tilde{T}_1^{(1)}(v + \tfrac{1}{2}i)\tilde{T}_1^{(1)}(v - \tfrac{1}{2}i) = \tilde{T}_2^{(1)}(v) + \tilde{T}_1^{(0)}(v)\tilde{T}_1^{(2)}(v). \quad (113)$$

4.4 Nonlinear integral equations

The thermodynamics of the spin- $\frac{1}{2}$ Heisenberg XXZ chain has recently been described by a nonlinear integral equation (NLIE) [179], which was rederived [180] from the T -system [146] of the QTM. It was also derived from a fugacity expansion [181]. There are similar NLIEs for other models [130, 131, 147, 148, 149]. Most importantly, the number of unknown functions for the NLIE is only one, corresponding to the rank of $su(2)$. In this subsection, we review the derivation of the $su(r+1)$ NLIE (123) from the T -system (109), in which only r unknown functions appear. This paves the way for the exact high temperature expansion to follow in section 4.5.

Numerical analysis for finite values of N , u_N and r reveals the expectation that the largest eigenvalue of the QTM (94) at $v = 0$ is given in terms of a one-string solution (for each colour $a = 1, 2, \dots, r$) of the Bethe equations (102) in the sector $N/2 = M_1 = M_2 = \dots = M_r$. From now on, we consider only this one-string solution. Thus $T_1^{(1)}(0)$ should give the largest eigenvalue Λ_1 . Numerical evidence for this conclusion is given in Appendix C. We thus state the following conjecture.

PROPOSITION 4.1 *For small u_N ($|u_N| \ll 1$), $a \in \{1, 2, \dots, r\}$, all zeros $\{\tilde{z}_1^{(a)}\}$ of $\tilde{T}_1^{(a)}(v)$ are located outside the physical strip $\text{Im}v \in [-\frac{1}{2}, \frac{1}{2}]$. In particular, they are located near the lines $\text{Im}v = \pm\frac{1}{2}(1+a)$, at least for the case $\mu_1 = \mu_2 = \dots = \mu_{r+1} = 0$.*

This conjecture is expected to be valid even in the Trotter limit $N \rightarrow \infty$. Now $\tilde{T}_m^{(a)}(v)$ has poles only at $\pm\tilde{\beta}_m^{(a)}$, where $\tilde{\beta}_m^{(a)} = \frac{1}{2}i(m+a) + iu_N$, whose order is at most $N/2$. Moreover,

$$Q_1^{(a)} = \lim_{|v| \rightarrow \infty} \tilde{T}_1^{(a)}(v) = \sum_{1 \leq i_1 < i_2 < \dots < i_a \leq r+1} e^{-\frac{\mu_{i_1}}{T}} e^{-\frac{\mu_{i_2}}{T}} \dots e^{-\frac{\mu_{i_a}}{T}} \quad (114)$$

is a finite number. This quantity is related to a solution of a functional relation called the Q -system [182, 183], for which $(Q_m^{(a)})^2 = Q_{m-1}^{(a)} Q_{m+1}^{(a)} + Q_m^{(a-1)} Q_m^{(a+1)}$, where $m \in \mathbb{Z}_{\geq 1}$ and $a \in \{1, 2, \dots, r\}$.

In the $su(4)$ case, we have

$$Q_1^{(1)} = e^{-\frac{\mu_1}{T}} + e^{-\frac{\mu_2}{T}} + e^{-\frac{\mu_3}{T}} + e^{-\frac{\mu_4}{T}}$$

$$\begin{aligned}
Q_1^{(2)} &= e^{-\frac{\mu_1+\mu_2}{T}} + e^{-\frac{\mu_1+\mu_3}{T}} + e^{-\frac{\mu_1+\mu_4}{T}} + e^{-\frac{\mu_2+\mu_3}{T}} + e^{-\frac{\mu_2+\mu_4}{T}} + e^{-\frac{\mu_3+\mu_4}{T}} \\
Q_1^{(3)} &= e^{-\frac{\mu_1+\mu_2+\mu_3}{T}} + e^{-\frac{\mu_1+\mu_2+\mu_4}{T}} + e^{-\frac{\mu_1+\mu_3+\mu_4}{T}} + e^{-\frac{\mu_2+\mu_3+\mu_4}{T}} \\
Q_1^{(4)} &= e^{-\frac{\mu_1+\mu_2+\mu_3+\mu_4}{T}}.
\end{aligned} \tag{115}$$

It follows that we must put

$$\tilde{T}_1^{(a)}(v) = Q_1^{(a)} + \sum_{j=1}^{N/2} \left\{ \frac{b_j^{(a)}}{(v - \tilde{\beta}_1^{(a)})^j} + \frac{\bar{b}_j^{(a)}}{(v + \tilde{\beta}_1^{(a)})^j} \right\} \tag{116}$$

where the coefficients $b_j^{(a)}, \bar{b}_j^{(a)} \in \mathbb{C}$ are given by the contour integrals

$$\begin{aligned}
b_j^{(a)} &= \oint_{C^{(a)}} \frac{dv}{2\pi i} \tilde{T}_1^{(a)}(v) (v - \tilde{\beta}_1^{(a)})^{j-1} \\
\bar{b}_j^{(a)} &= \oint_{\bar{C}^{(a)}} \frac{dv}{2\pi i} \tilde{T}_1^{(a)}(v) (v + \tilde{\beta}_1^{(a)})^{j-1}.
\end{aligned} \tag{117}$$

The contour $C^{(a)}$ is a counterclockwise closed loop around $\tilde{\beta}_1^{(a)}$ which does not encircle $-\tilde{\beta}_1^{(a)}$. Similarly the contour $\bar{C}^{(a)}$ is a counterclockwise closed loop around $-\tilde{\beta}_1^{(a)}$ not encircling $\tilde{\beta}_1^{(a)}$.

Using the T -system (109), the integrals (117) can be modified to read

$$\begin{aligned}
b_j^{(a)} &= \oint_{C^{(a)}} \frac{dv}{2\pi i} \left\{ \frac{\tilde{T}_2^{(a)}(v - \frac{1}{2}i)}{\tilde{T}_1^{(a)}(v - i)} \right. \\
&\quad \left. + \frac{\tilde{T}_1^{(a-1)}(v - \frac{1}{2}i) \tilde{T}_1^{(a+1)}(v - \frac{1}{2}i)}{\tilde{T}_1^{(a)}(v - i)} \right\} (v - \tilde{\beta}_1^{(a)})^{j-1} \\
\bar{b}_j^{(a)} &= \oint_{\bar{C}^{(a)}} \frac{dv}{2\pi i} \left\{ \frac{\tilde{T}_2^{(a)}(v + \frac{1}{2}i)}{\tilde{T}_1^{(a)}(v + i)} \right. \\
&\quad \left. + \frac{\tilde{T}_1^{(a-1)}(v + \frac{1}{2}i) \tilde{T}_1^{(a+1)}(v + \frac{1}{2}i)}{\tilde{T}_1^{(a)}(v + i)} \right\} (v + \tilde{\beta}_1^{(a)})^{j-1}.
\end{aligned} \tag{118}$$

Substitution of (118) into (116) and performing the summation over j then gives

$$\tilde{T}_1^{(a)}(v) = Q_1^{(a)}$$

$$\begin{aligned}
& + \oint_{C^{(a)}} \frac{dy}{2\pi i} \frac{1 - \left(\frac{y}{v - \tilde{\beta}_1^{(a)}}\right)^{N/2}}{v - y - \tilde{\beta}_1^{(a)}} \left\{ \frac{\tilde{T}_2^{(a)}(y + \tilde{\beta}_1^{(a)} - \frac{1}{2}i)}{\tilde{T}_1^{(a)}(y + \tilde{\beta}_1^{(a)} - i)} \right. \\
& \quad \left. + \frac{\tilde{T}_1^{(a-1)}(y + \tilde{\beta}_1^{(a)} - \frac{1}{2}i)\tilde{T}_1^{(a+1)}(y + \tilde{\beta}_1^{(a)} - \frac{1}{2}i)}{\tilde{T}_1^{(a)}(y + \tilde{\beta}_1^{(a)} - i)} \right\} \\
& + \oint_{\overline{C}^{(a)}} \frac{dy}{2\pi i} \frac{1 - \left(\frac{y}{v + \tilde{\beta}_1^{(a)}}\right)^{N/2}}{v - y + \tilde{\beta}_1^{(a)}} \left\{ \frac{\tilde{T}_2^{(a)}(y - \tilde{\beta}_1^{(a)} + \frac{1}{2}i)}{\tilde{T}_1^{(a)}(y - \tilde{\beta}_1^{(a)} + i)} \right. \\
& \quad \left. + \frac{\tilde{T}_1^{(a-1)}(y - \tilde{\beta}_1^{(a)} + \frac{1}{2}i)\tilde{T}_1^{(a+1)}(y - \tilde{\beta}_1^{(a)} + \frac{1}{2}i)}{\tilde{T}_1^{(a)}(y - \tilde{\beta}_1^{(a)} + i)} \right\} \quad (119)
\end{aligned}$$

for $a \in \{1, 2, \dots, r\}$ and $m \in \mathbb{Z}_{\geq 1}$. Here the contour $C^{(a)}$ (resp. $\overline{C}^{(a)}$) is a counterclockwise closed loop around the origin which does not encircle $-2\tilde{\beta}_1^{(a)}$ (resp. $2\tilde{\beta}_1^{(a)}$). There are cancellations of singularities in the denominator and the numerator in each term in the first curly bracket $\{\dots\}$ in (119). The poles in the first term in the first bracket are $-2\tilde{\beta}_1^{(a)}$ and $\tilde{z}_1^{(a)} - \tilde{\beta}_1^{(a)} + i$; the poles in the second term in the first bracket are $0, -2\tilde{\beta}_1^{(a)}$ and $\tilde{z}_1^{(a)} - \tilde{\beta}_1^{(a)} + i$. Thus the contribution to the contour integral from the first term in the first bracket vanishes if the contour $C^{(a)}$ does not encircle the pole at $\tilde{z}_1^{(a)} - \tilde{\beta}_1^{(a)} + i$ (cf. Conjecture 4.1). As for the second curly bracket in (119), the poles in the first term are $2\tilde{\beta}_1^{(a)}$ and $\tilde{z}_1^{(a)} + \tilde{\beta}_1^{(a)} - i$; the poles in the second term are $0, 2\tilde{\beta}_1^{(a)}$ and $\tilde{z}_1^{(a)} + \tilde{\beta}_1^{(a)} - i$. Thus the contribution to the contour integral from the first term in the second bracket vanishes if the contour $\overline{C}^{(a)}$ does not encircle the pole at $\tilde{z}_1^{(a)} + \tilde{\beta}_1^{(a)} - i$.

It therefore follows that (119) reduces to

$$\begin{aligned}
& \tilde{T}_1^{(a)}(v) = Q_1^{(a)} \\
& + \oint_{C^{(a)}} \frac{dy}{2\pi i} \frac{1 - \left(\frac{y}{v - \tilde{\beta}_1^{(a)}}\right)^{N/2}}{v - y - \tilde{\beta}_1^{(a)}} \frac{\tilde{T}_1^{(a-1)}(y + \tilde{\beta}_1^{(a)} - \frac{1}{2}i)\tilde{T}_1^{(a+1)}(y + \tilde{\beta}_1^{(a)} - \frac{1}{2}i)}{\tilde{T}_1^{(a)}(y + \tilde{\beta}_1^{(a)} - i)} \\
& + \oint_{\overline{C}^{(a)}} \frac{dy}{2\pi i} \frac{1 - \left(\frac{y}{v + \tilde{\beta}_1^{(a)}}\right)^{N/2}}{v - y + \tilde{\beta}_1^{(a)}} \frac{\tilde{T}_1^{(a-1)}(y - \tilde{\beta}_1^{(a)} + \frac{1}{2}i)\tilde{T}_1^{(a+1)}(y - \tilde{\beta}_1^{(a)} + \frac{1}{2}i)}{\tilde{T}_1^{(a)}(y - \tilde{\beta}_1^{(a)} + i)} \quad (120)
\end{aligned}$$

for $a \in \{1, 2, \dots, r\}$. Here the contour $C^{(a)}$ (resp. $\overline{C}^{(a)}$) is a counterclockwise

closed loop around the origin not encircling $\tilde{z}_1^{(a)} - \tilde{\beta}_1^{(a)} + i, -2\tilde{\beta}_1^{(a)}$ (resp. $\tilde{z}_1^{(a)} + \tilde{\beta}_1^{(a)} - i, 2\tilde{\beta}_1^{(a)}$). The poles at $y = 0$ in $\tilde{T}_1^{(a-1)}(y \pm \tilde{\beta}_1^{(a)} \mp \frac{1}{2}i)$ are cancelled by the zeros at $y = 0$ in $(\frac{y}{v \mp \tilde{\beta}_1^{(a)}})^{N/2}$. Thus (120) is further simplified to

$$\begin{aligned} \tilde{T}_1^{(a)}(v) &= Q_1^{(a)} \\ &+ \oint_{C^{(a)}} \frac{dy}{2\pi i} \frac{\tilde{T}_1^{(a-1)}(y + \tilde{\beta}_1^{(a)} - \frac{1}{2}i) \tilde{T}_1^{(a+1)}(y + \tilde{\beta}_1^{(a)} - \frac{1}{2}i)}{(v - y - \tilde{\beta}_1^{(a)}) \tilde{T}_1^{(a)}(y + \tilde{\beta}_1^{(a)} - i)} \\ &+ \oint_{\bar{C}^{(a)}} \frac{dy}{2\pi i} \frac{\tilde{T}_1^{(a-1)}(y - \tilde{\beta}_1^{(a)} + \frac{1}{2}i) \tilde{T}_1^{(a+1)}(y - \tilde{\beta}_1^{(a)} + \frac{1}{2}i)}{(v - y + \tilde{\beta}_1^{(a)}) \tilde{T}_1^{(a)}(y - \tilde{\beta}_1^{(a)} + i)} \end{aligned} \quad (121)$$

for $a \in \{1, 2, \dots, r\}$.

This is the NLIE for finite Trotter number. The next important step is to take the Trotter limit $N \rightarrow \infty$. Define $\mathcal{T}_1^{(a)}(v) = \lim_{N \rightarrow \infty} \tilde{T}_1^{(a)}(v)$, then

$$\mathcal{T}_1^{(0)}(v) = \exp \left(\frac{J_{\parallel}}{(v^2 + \frac{1}{4})T} \right). \quad (122)$$

Finally, we have arrived at a system of NLIE which contains only a *finite* number of unknown functions, $\{\mathcal{T}_1^{(a)}(v)\}_{1 \leq a \leq r}$, namely

$$\begin{aligned} \mathcal{T}_1^{(a)}(v) &= Q_1^{(a)} + \oint_{C^{(a)}} \frac{dy}{2\pi i} \frac{\mathcal{T}_1^{(a-1)}(y + \beta_1^{(a)} - \frac{1}{2}i) \mathcal{T}_1^{(a+1)}(y + \beta_1^{(a)} - \frac{1}{2}i)}{(v - y - \beta_1^{(a)}) \mathcal{T}_1^{(a)}(y + \beta_1^{(a)} - i)} \\ &+ \oint_{\bar{C}^{(a)}} \frac{dy}{2\pi i} \frac{\mathcal{T}_1^{(a-1)}(y - \beta_1^{(a)} + \frac{1}{2}i) \mathcal{T}_1^{(a+1)}(y - \beta_1^{(a)} + \frac{1}{2}i)}{(v - y + \beta_1^{(a)}) \mathcal{T}_1^{(a)}(y - \beta_1^{(a)} + i)} \end{aligned} \quad (123)$$

for $a \in \{1, 2, \dots, r\}$. Here $\mathcal{T}_1^{(r+1)}(v) = \exp(-(\mu_1 + \dots + \mu_{r+1})/T)$. The contour $C^{(a)}$ (resp. $\bar{C}^{(a)}$) is a counterclockwise closed loop around the origin such that $y \neq v - \beta_1^{(a)}$ (resp. $y \neq v + \beta_1^{(a)}$) and it does not encircle $z_1^{(a)} - \beta_1^{(a)} + i, -2\beta_1^{(a)}$ (resp. $z_1^{(a)} + \beta_1^{(a)} - i, 2\beta_1^{(a)}$), where $z_1^{(a)} = \lim_{N \rightarrow \infty} \tilde{z}_1^{(a)}$.

In particular, for the $su(4)$ case, the NLIEs are

$$\mathcal{T}_1^{(1)}(v) = Q_1^{(1)} + \oint_{C^{(1)}} \frac{dy}{2\pi i} \frac{\exp \left(\frac{J_{\parallel}}{y(y+i)T} \right) \mathcal{T}_1^{(2)}(y + \frac{1}{2}i)}{(v - y - i) \mathcal{T}_1^{(1)}(y)}$$

$$\begin{aligned}
& + \oint_{\bar{C}^{(1)}} \frac{dy}{2\pi i} \frac{\exp\left(\frac{J_{\parallel}}{y(y-i)T}\right) \mathcal{T}_1^{(2)}(y - \frac{1}{2}i)}{(v - y + i)\mathcal{T}_1^{(1)}(y)} \\
\mathcal{T}_1^{(2)}(v) &= Q_1^{(2)} + \oint_{C^{(2)}} \frac{dy}{2\pi i} \frac{\mathcal{T}_1^{(1)}(y + i)\mathcal{T}_1^{(3)}(y + i)}{(v - y - \frac{3}{2}i)\mathcal{T}_1^{(2)}(y + \frac{1}{2}i)} \\
& + \oint_{\bar{C}^{(2)}} \frac{dy}{2\pi i} \frac{\mathcal{T}_1^{(1)}(y - i)\mathcal{T}_1^{(3)}(y - i)}{(v - y + \frac{3}{2}i)\mathcal{T}_1^{(2)}(y - \frac{1}{2}i)} \\
\mathcal{T}_1^{(3)}(v) &= Q_1^{(3)} + e^{-\frac{\mu_1 + \mu_2 + \mu_3 + \mu_4}{T}} \oint_{C^{(3)}} \frac{dy}{2\pi i} \frac{\mathcal{T}_1^{(2)}(y + \frac{3}{2}i)}{(v - y - 2i)\mathcal{T}_1^{(3)}(y + i)} \\
& + e^{-\frac{\mu_1 + \mu_2 + \mu_3 + \mu_4}{T}} \oint_{\bar{C}^{(3)}} \frac{dy}{2\pi i} \frac{\mathcal{T}_1^{(2)}(y - \frac{3}{2}i)}{(v - y + 2i)\mathcal{T}_1^{(3)}(y - i)} \quad (124)
\end{aligned}$$

where $Q_1^{(a)}$ are given in (115).

The free energy per site follows from (123) and the relation

$$f = J_{\parallel} - T \ln \mathcal{T}_1^{(1)}(0). \quad (125)$$

4.5 High temperature expansion

We now turn to the calculation of the high temperature expansion of the free energy (125) from the NLIE (123). In the $su(2)$ case (the isotropic Heisenberg chain), the high temperature expansion of the free energy was calculated from the NLIE [179] up to order 100 [129]. The first step is to assume the expansion

$$\mathcal{T}_1^{(a)}(v) = \exp\left(\sum_{n=0}^{\infty} b_n^{(a)}(v) \left(\frac{J_{\parallel}}{T}\right)^n\right), \quad a \in \{1, 2, \dots, r\} \quad (126)$$

for large T . In contrast to the $su(2)$ case [129], poles in the coefficients $\{b_n^{(a)}(v)\}$ have to be taken into account. This requires the further assumption,

$$b_n^{(a)}(v) = \sum_{j=0}^{n-1} \frac{c_{n,j}^{(a)} v^{2j}}{(v^2 + \frac{(a+1)^2}{4})^n} \quad (127)$$

where the coefficients $c_{n,j}^{(a)}$ do not depend on v . In general, these coefficients are rational functions of $Q_1^{(a)}$ given in (114) and thus they are T -dependent.

The coefficients $b_n^{(a)}(v)$ are obtained by substituting (126) into (123), with $b_0^{(a)}(v) = \log Q_1^{(a)}$.

For the $su(4)$ case relevant to the integrable ladder model the first few terms of the free energy are given by [131]

$$-\frac{1}{T}f(T, H) = \ln Q_1^{(1)} + c_{1,0}^{(1)} \left(\frac{J}{T}\right) + c_{2,0}^{(1)} \left(\frac{J}{T}\right)^2 + c_{3,0}^{(1)} \left(\frac{J}{T}\right)^3 + \dots \quad (128)$$

The coefficients $c_{n,0}^{(1)}$ are given up to order $n = 5$ in Appendix A. The key point for the ladder model is the quantity $Q_1^{(a)}$ given in (115) which involves the chemical potentials.

The advantage of this approach is that the thermal and magnetic properties can be evaluated directly from the exact free energy expression (128) using the standard relations

$$M = -\frac{\partial f(T, H)}{\partial H} \Big|_T, \quad \chi = -\frac{\partial^2 f(T, H)}{\partial H^2} \Big|_T, \quad C = -T \frac{\partial^2 f(T, H)}{\partial T^2} \Big|_H \quad (129)$$

which define the magnetization, the magnetic susceptibility and the magnetic specific heat.

5 Thermodynamics of the spin- $\frac{1}{2}$ ladder compounds

Although many two-leg ladders have been synthesised and extensively studied, the critical points have been measured only for a few strong coupling compounds with accessible gaps. Theoretical results for the two-leg spin- $\frac{1}{2}$ ladder model have been mainly focussed on the thermal and magnetic properties of the standard Heisenberg ladder. According to a celebrated result from perturbation theory [63, 64, 20], the first-order terms for the zero temperature gap Δ and the critical field H_{c2} are given by $\Delta = J_\perp - J_\parallel$ and $\mu_B g H_{c2} = J_\perp + 2J_\parallel$, which are seen to be in good agreement with the experimental results for some strong coupling compounds [20]. In addition, the susceptibility as a function of temperature, $\chi \propto e^{-\Delta/T}/\sqrt{T}$, derived from the quantum transfer matrix algorithm [66] is generally used to fit the susceptibility of the two-leg ladder compounds.

In comparison with perturbation theory or numerical and analytic methods [31, 162, 163, 27, 184] applied to ladder-like systems, the integrable ladder model (3) [92, 116, 117, 8, 152] has a distinct advantage for studying phase diagrams and quantities such as the high field magnetization, specific heat and susceptibility, as they follow directly from the exact free energy. Moreover, the

Compounds	B5i2aT	Cu(Hp)Cl	BPCB	BIP-BNO	CuCON
HSL $J_{\perp}$	13.0 K	13.1 K	13.3 K	72 K	509 K

TBA H_{c2}	10.02 T	13.1 T	14.1 T	83 T	389 T

Table 1. The coupling strengths, $J_{\perp}$ and $J_{\parallel}$, and critical field values, H_{c1} and H_{c2} obtained from previous fits with the Heisenberg spin ladder (HSL) and for the integrable spin ladder (ISL) using the TBA approach for some strong coupling ladder compounds (see text).

ground state properties at zero temperature are now understood by means of the TBA [116, 117]. As demonstrated in section 3, the critical fields, $H_{c1} = (J_{\perp} - 4J_{\parallel})/\mu_B g$ and $H_{c2} = (J_{\perp} + 4J_{\parallel})/\mu_B g$, also give a good fit for the strong coupling compounds. The coupling constants $J_{\perp}$ and $J_{\parallel}$ can be fixed by fitting experimental results for the susceptibility and the magnetization. In general, these coupling constants cannot be fixed from a good fit just to the susceptibility, as it determines only the amplitude of the gap. The way to determine the coupling constants has been discussed at the beginning of section 3.3. In general the values suggested from only the critical fields are not the best for fitting. The coupling constants should provide a good overall fit for each of thermodynamic properties. In the following we apply the integrable model approach to the compounds $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$ [42], bis 5-iodo-2-aminopyridinium tetrabromocuprate (II) dihydrate (abbreviated B5i2aT), $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$ (abbreviated CuHpCl) [43, 44, 45], $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$ (abbreviated BPCB) [47], BIP-BNO [159, 160] and $[\text{Cu}_2(\text{C}_2\text{O}_2)(\text{C}_{10}\text{H}_8\text{N}_2)_2](\text{NO}_3)_2$ (abbreviated CuCON) [161].

Values for the critical fields, obtained from the integrable spin ladder (ISL) via TBA at zero temperature [116, 117], are compared with the experimental results for the Heisenberg spin ladder model (HSL) at low temperature in table 1. The small discrepancy between the TBA critical fields at zero temperature and experimental critical fields at low temperature is a finite temperature effect. As the temperature increases the energy gap decreases due to triplet excitations, as the energy gap is a measure of the energy cost of the first triplet excitation at zero temperature. The experimental gap is determined by the first critical field H_{c1} at low temperatures. It will be seen below that the thermal and magnetic properties derived from the HTE are in excellent agreement with the experimental results.

5.1 Note on conversion constants

Before turning to the study of the thermodynamics of these compounds via the HTE, a remark on conversion constants is in order. Overall conversion constants for the susceptibility, the specific heat and the magnetization are needed due to the fact that the T -system (109) is specified up to normalization. Therefore, in order to match the experimental data for the unnormalized magnetic properties, a scaling factor needs to be fixed for the magnetic properties, such as the magnetization, susceptibility, specific heat and magnetic entropy. In the following, we will see that the conversion constant $\chi_{\text{HTE}} \approx 0.40615\chi_{\text{EXP}}$ for the susceptibility of the ladder compounds is half that of the spin-1 chain compounds [153, 154] due to there being $2L$ spins in the ladder model. The specific heat conversion constant is material dependent due to the choice of experimental units. However, for normalized magnetic properties, such as the magnetization (M/M_s), the conversion constant plays no role in fitting the experimental data.

From the derivation of the HTE it can be seen that the free energy expansion

$$f_{\text{HTE}}(T, H) = c_0 + c_1 \frac{J}{T} + c_2 \left(\frac{J}{T} \right)^2 + c_3 \left(\frac{J}{T} \right)^3 + \dots \quad (130)$$

is only fixed up to a normalisation constant, i.e.

$$f_{\text{phys.units}} = \gamma_{\text{conv.}} \cdot f_{\text{HTE}}(T, H). \quad (131)$$

Physically this amounts to the fact that the units of energy, temperature, external field and coupling strength are not unified in the theory, i.e., there is no analogue of a ‘characteristic length’. Mathematically, it can be traced back to the unit of temperature and the multiplicativity of the R -matrix of the model. The scaling factors for different magnetic quantities such as susceptibility, specific heat and magnetic entropy can be uniquely fixed by their corresponding experimental curves. They depend on their experimental units and are given in the following figure captions.

In the HTE calculations for physical properties this factor has previously been used to obtain a best fit for experimental data via vertical scaling. This procedure is open to critique, as it would offer a new free parameter, enabling a better fit than from the pure HTE theory. The conversion factor can in fact be calculated, leading to predictions of physical properties in physical units (SI) instead of arbitrary HTE units. One remaining problem is the widespread use of non-standard non-SI units in the experimental measurements. These measurements sometimes even depend on compound-specifics such as molecular mass. The problem of converting SI units to experimental units, while

often not trivial, is in no way related to the HTE method and will thus not be further discussed here. HTE predictions are made in SI units.

In eqns (130) and (131) the unknown constant $\gamma_{\text{conv.}}$ is a prefactor, i.e., the same in all orders of the expansion. The expansion is generated for interacting spins from the Bethe Ansatz solution. For zero order, the non-interacting case $J = 0$, the expansion reduces to the trivial (non Bethe Ansatz) case of L independent spins (here, e.g., a two site spin- $\frac{1}{2}$ system), for which

$$f_{\text{0th order}} = \gamma_{\text{conv.}} c_0 = -k_B T \ln \left(e^{\frac{\mu_1}{k_B T}} + e^{\frac{\mu_2}{k_B T}} \right). \quad (132)$$

The second equality holds for the special point $J = 0$, but since $\gamma_{\text{conv.}}$ is a constant it can be extended in eqns (130) and (131) to all $J > 0$.

Once the free energy is thus known in SI units, it is straightforward to obtain all other properties derived from it in SI units via

$$M_{\text{phys.units.}} = -\frac{\partial}{\partial H} f_{\text{phys.units.}} \quad (133)$$

The important point here is that the HTE method does make predictions in physical units, even if the original T -system is only fixed up to normalisation. Thus all conversion factors can in theory be calculated using the additional information from the non-interacting spin system or directly from fitting experimental curves.

In practice the HTE scheme is unable to access thermal and magnetic properties for temperature scales less than $J_{\parallel}$. At high temperatures the first few terms in the free energy expansion are sufficient to determine the thermodynamic properties. The HTE approach works best in practice for small ratios of $J_{\parallel}/T$, as only the lowest few terms of the series are needed to get a good agreement with the experimental results. Consequently for high temperatures and materials with a small coupling constant $J_{\parallel}$ even the zeroth order HTE suffices to capture the main physical properties. This lowest order corresponds to the approximation where $J_{\parallel} = 0$, sometimes called the rung-dimer model [185]. In this case the ground state wavefunction is a simple product of rung singlets. To this order the partition function of the ladder model consists of only four terms (see the first term of the Q -system for comparison) and can be evaluated directly without the use of the integrable theory. However, not all interesting physical properties can be captured by this simple dimer model, which is the zeroth order of the HTE series. Especially as much of the physics of interest lies in the lower temperature regime, with the parameter $J_{\parallel}$ material dependent and not necessarily small enough for the dimer approximation.

Figure 11 shows a comparison of the magnetization curve at two different temperatures for the ladder compound $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$. It can be seen that

Figure 11. Comparison between the dimer approximation (0th order HTE) and the 5th order HTE result for the magnetization of the compound $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$. The dimer approximation does not distinguish the two critical field values, for which the experimental difference is $H_{c1} - H_{c1} \approx 7 \text{ T}$ (see text).

the zeroth order approximation of the pure dimer model captures the qualitative shape of the curve, whereas the HTE series result (discussed further in figure 20) is in quantitative agreement with the experimental measurement. The dimer model is obviously a bad approximation for this compound, as the two critical fields, namely $H_{c1} = 7 \text{ T}$ and $H_{c2} = 14.1 \text{ T}$ are far apart. The difference between these values is proportional to the coupling $J_{\parallel}$, which the dimer model neglects.

We proceed now to the comparison with the experimental data for a number of compounds.

5.2 $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$

5.2.1 Susceptibility. Measurement of the susceptibility and magnetization of the compound B5i2aT [42] suggests that it lies in the strong coupling regime, with coupling constants $J_{\perp} = 13.0 \text{ K}$, $J_{\parallel} = 1.15 \text{ K}$ for the standard Heisenberg ladder. From the application of the HTE for the Hamiltonian (3) we find that the coupling constants $J_{\perp} = 13.3 \text{ K}$ and $J_{\parallel} = 0.2875 \text{ K}$ give excellent fits to both the susceptibility and the magnetization. The temperature dependence of the susceptibility curves is given in figure 12, where the solid line denotes the susceptibility derived from the free energy (128) with up to fifth order

Figure 12. Susceptibility versus temperature for the compound B5i2aT. Circles denote the experimental data [42] and the solid curve is the susceptibility evaluated directly from the HTE at $H = 1$ T. A parameter fit suggests the coupling constants $J_{\perp} = 13.3$ K and $J_{\parallel} = 0.2875$ K with $g = 2.1$ and $\mu_B = 0.672$ K/T. The inset shows the same fit in the susceptibility at low temperature. The conversion constant is $\chi_{\text{HTE}} \approx 0.40615\chi_{\text{EXP}}$.

of HTE. An overall excellent fit with the experimental susceptibility curve is observed. The typical rounded peak in the zero magnetic field susceptibility curve, characteristic of a low dimensional antiferromagnet, is seen around 8.1 K. The susceptibility exponentially decreases with further decrease of the temperature toward zero. The TBA analysis suggests an energy gap $\Delta \approx 8.6$ T.

The low temperature behaviour of the magnetic susceptibility, shown in the inset of figure 12, is also in excellent agreement with the experimental data. We observed that the magnetic field raises the susceptibility due to the lower triplet component being energetically favoured by the magnetic field at low temperature. If the magnetic field is much smaller than the temperature, there is no significant change to the susceptibility.

5.2.2 High field magnetization. The behaviour of the field dependent magnetization curve can lead to the prediction of the low temperature phase diagram as well as the magnetization plateaux. It follows that the magnetization is a particular interesting quantity for studying critical behaviour. The high field magnetization curves evaluated from the HTE at different temperatures are shown in figure 13 in comparison with the experimental curves, with which there is also excellent agreement. At very low temperature, provided the magnetic field is less than the critical field H_{c1} , the rung singlet forms a singlet

Figure 13. Magnetization versus magnetic field indicating the high field quantum phase diagram for the compound B5i2aT with the same constants as in Fig.12. The discrepancy in magnetization curves at $T = 0.4$ K and $T = 1.59$ K is due to paramagnetic impurities, which result in nonzero magnetization in the singlet ground state. This impurity effect becomes negligible at higher temperatures. The inset shows the one point correlation function vs magnetic field – at low temperature the singlet ground state can be clearly identified.

ground state. The antiferromagnetic correlation length is finite while the triplet state is gapful. At finite temperature the triplet excitations become involved so that the gap decreases with increasing temperature. This behaviour is observed in the high field magnetization curves at $T = 1.59$ K and $T = 4.35$ K presented in figure 13. The gap closes at the critical field $H_{c1} = \Delta/\mu_B g$. If the magnetic field is above the critical point H_{c1} , the lower component of the triplet becomes involved in the ground state. At zero temperature, one can show rigorously that the other two (higher) components of the triplet never become involved in the ground state. Therefore, in this vicinity, the strongly coupled two-leg ladder can be mapped to the XXZ Heisenberg chain with an effective magnetic field term, as done in section 3 and in [64, 67]. The magnetization increases almost linearly with the field towards the critical point H_{c2} , at which the ground state becomes fully polarized. In addition, the inflection point is indicated at $H_{IP} \approx J_{\perp}/\mu_B g$ where the magnetization moment is equal to 0.5. At $T = 0.4$ K, the HTE magnetization curve indicates that $H_{c1} \approx 8.6$ T and $H_{c2} \approx 10.02$ T. These values are in excellent agreement with the experimental estimates of $H_{c1} = 8.3$ T and $H_{c2} = 10.4$ T. The experimental magnetization in the singlet ground state at low temperature appears to be nonzero. This is caused by paramagnetic impurities due to the synthesis process.

The inflection point is clearly visible in the experimental magnetization curves for the compound B5i2aT [42]. It follows that for the strong coupling ladder compounds at zero temperature, the one point correlation function

$\langle S_j \cdot T_j \rangle = -\frac{3}{4}$ lies in a gapped singlet groundstate, which indicates an ordered dimer phase, while $\langle S_j \cdot T_j \rangle = \frac{1}{4}$ in the fully-polarized ferromagnetic phase. However, in a Luttinger liquid phase $\langle S_j \cdot T_j \rangle = -\frac{3}{4} + S^z$ and the magnetic field increases the one point correlation function. At low temperatures $T < J_{\parallel}$ the one point correlation function is given by $\langle S_j \cdot T_j \rangle = \frac{1}{4} + \left(\frac{d}{dJ_{\perp}} f(T, H) \right)_T$. The field-induced quantum phase transition can be clearly seen from the one point correlation function curves at different temperatures (see the inset of figure 13): in the region $H < H_{c1}$, the correlation functions $\langle S_j \cdot T_j \rangle = -\frac{3}{4}$ indicate a gapped singlet groundstate; in the region $H > H_{c2}$, the correlation functions $\langle S_j \cdot T_j \rangle = \frac{1}{4}$ correspond to a fully polarized ferromagnetic state; while for $H_{c1} < H < H_{c2}$, the one point correlation function $-\frac{3}{4} < \langle S_j \cdot T_j \rangle < \frac{1}{4}$ indicates a magnetic Luttinger phase.

5.3 $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$

5.3.1 Magnetic susceptibility. The ladder compound $\text{Cu}(\text{Hp})\text{Cl}$ has been extensively studied, both experimentally and theoretically, including several numerical-based calculations [44, 45, 65, 162, 184, 59, 64, 187, 188, 189, 8, 116, 117, 152]. Nevertheless, the thermodynamic quantities of the model, such as the high field magnetization, the full temperature susceptibility, the magnetic specific heat, the entropy and the correlation length, are worth close examination via the TBA and HTE methods. Here we show that the integrable model provides an efficient way of investigating the thermodynamics of this compound. The solid line in figure 14 shows the zero field magnetic susceptibility curve obtained by HTE with up to fifth order terms. The rounded hump is observed around $T = 8.0 \text{ K}$. A full fit with the experimental curve for the susceptibility of Hamiltonian (3) suggests the values $J_{\perp} = 14.5 \text{ K}$ and $J_{\parallel} = 1.0 \text{ K}$ with $g = 2.1$, which lies in the same phase as the conventional Heisenberg ladder model [64]. The TBA gap $\Delta \approx 10.5 \text{ K}$ agrees well with the experimental gap $\Delta = 10.9 \text{ K}$ [44, 45, 65].

At this point it is appropriate to remark on the convergence of the HTE series. The HTE in equation (126) is not a series in the usual Taylor sense. Here the expansion parameter is $J_{\parallel}/T$. For a given compound $J_{\parallel}$ is fixed, with $J_{\parallel}/T$ a small parameter at high temperatures. It is important to note that the expansion coefficients $c_{ij}^{(k)}$ depend on the temperature through the Q -system, which in turn depends on the chemical potentials, see equations (114) and (115). For this more sophisticated type of series expansion it suffices to consider only the first few terms in the physically interesting regime. When the expansion parameter is no longer small, adding higher order terms does not improve the fit significantly. In the following numerical example we show

Figure 14. Susceptibility versus temperature for the compound Cu(Hp)Cl. Circles represent the experimental data [59]. The solid curve is the susceptibility evaluated directly from the HTE with $\mu_B = 0.672 \text{ K/T}$, $J_\perp = 14.5 \text{ K}$, $J_\parallel = 1.0 \text{ K}$ and $g = 2.1$. The conversion constant is $\chi_{\text{HTE}} \approx 0.40615 \chi_{\text{EXP}}$.

this behavior for a generic case, namely the particular compound Cu(Hp)Cl under consideration (figure 14). For the susceptibility $\chi(T)$ the relative error in using the HTE up to third order and up to fifth order compared to using up to ninth order terms (as an example of higher order terms) for some sample temperatures is given in the following table.

T	2 K	5 K	10 K	50 K
error χ_{1-3} rel. to χ_{1-9}	7.33%	0.122%	0.0003288%	$< 9.2 \cdot 10^{-7}\%$
error χ_{1-5} rel. to χ_{1-9}	0.56%	0.00147%	$3.8 \cdot 10^{-6}\%$	$< 5.2 \cdot 10^{-10}\%$

In this article for comparison with experimental data we have used the HTE expansion with up to 5th order terms. Technically it is not harder to include higher order HTE terms in the analysis. The computation of the coefficients in Appendix A has to be done only once, as the expansion formula gives the coefficients in terms of the abstract Q -system. For each compound or new fit only the numerical values have to be fed into the chemical potentials, allowing an immediate calculation of all physical properties up to the order of the initial free energy expansion.

In principle, the range of validity of the HTE can be extended to low temperatures via Padé series analysis. This uses the fact that the free energy expression is a smooth function of its arguments.

5.3.2 Magnetic specific heat and entropy. The solid and dashed lines in figure 15 denote the specific heat curves at $H = 0 \text{ T}$ and 4 T obtained from the

Figure 15. Specific heat versus temperature at different magnetic field values for the compound $\text{Cu}(\text{Hp})\text{Cl}$ with the same coupling constants $J_{\perp}$, $J_{\parallel}$ and g as in figure 14. The experimental data [59] is given by circles for $H = 0$ T and triangles for $H = 4$ T. The solid and dashed curves are evaluated from the HTE for these same magnetic field values. The conversion constant is $C_{\text{HTE}} \approx 4.515 C_{\text{EXP}}$ (J/mol-Cu-K).

HTE with the same coupling constants as in figure 14. They agree well with the experimental data [59]. A rounded peak indicating short range ordering is observed around $T = 4.5$ K. At temperatures below $T = 4.5$ K there is an exponential decay which is believed to be due to an ordered phase. A similar fit for the specific heat at $H = 2$ T and 6 T is observed in figure 16. Another peak is found around $T = 1$ K for the magnetic field $H = 6$ T. This is mainly because the HTE is not convergent for this model if the temperature is less than 1 K. At these values the temperature scale is comparable to the coupling $J_{\parallel} = 1.0$ K. Adding further HTE terms is not sufficient to overcome such kinds of divergency. The entropy has been calculated directly from the free energy (128) with up to fifth order terms. Figure 17 shows agreement with the experimental entropy curves [59]. A discrepancy with the fitting is observed for high magnetic field, which is probably caused by paramagnetic impurity effects.

5.3.3 High field magnetization. From table 1, we see that the parameter fitting values $J_{\perp} = 14.5$ K and $J_{\parallel} = 1.0$ K lead to the critical field values $H_{c1} = 7.4$ T and $H_{c2} = 13.1$ T, which are in good agreement with the experimental values $H_{c1} = 7.5$ T and $H_{c2} = 13.0$ T. The experimental high field magnetization has been measured by different groups [64, 65]. The zero temperature TBA magnetization curve (red dashed line) in figure 18 indicates the critical field values in the proximity of the lowest temperature data at

Figure 16. Specific heat versus temperature for the compound Cu(Hp)Cl, now for the experimental data for $H = 2$ T and $H = 6$ T [59]. We use the same coupling constants as in figure 14 and figure 15. The solid and dashed curves are evaluated from the HTE for these same magnetic field values. The conversion constant is $C_{\text{HTE}} \approx 4.515 C_{\text{EXP}}$ (J/mol-Cu-K).

Figure 17. Entropy vs temperature comparison between theory and experimental data [59] for the compound Cu(Hp)Cl at the external magnetic field values $H = 0$ T, $H = 4$ T and $H = 6$ T. The coupling constants are the same as in the previous figures for Cu(Hp)Cl. The solid, dashed and dot-dashed curves evaluated from the HTE for these same magnetic field values. A discrepancy with the experimental entropy data for high external magnetic field is observed, probably due to paramagnetic impurities. The conversion constant is $S_{\text{HTE}} \approx 4.153 S_{\text{EXP}}$ (J/mol-Cu-K).

$T = 0.42$ K [64]. We cannot evaluate the magnetization directly from the HTE for temperatures lower than $T = 1.5$ K due to the lack of convergence. At the higher temperatures $T = 12.3$ K and $T = 4.04$ K the HTE magnetization curves fits are seen to fit the experimental data well. At low temperatures

Figure 18. Magnetization vs magnetic field comparison between theory and experimental data [64] for the compound $\text{Cu}(\text{Hp})\text{Cl}$ for varying temperature. The TBA with the same coupling constants, $J_{\perp} = 14.5 \text{ K}$, $J_{\parallel} = 1.0 \text{ K}$ and $g = 2.1$, predicts critical fields at zero temperature which coincide with the experimental values at low temperature. The magnetization curves evaluated from the HTE give satisfactory agreement with the experimental curves.

$T = 1.6 \text{ K}$ and $T = 2.44 \text{ K}$, a small discrepancy between the HTE and experimental curves is observed. This is mainly because the coupling constants $J_{\perp} = 14.5 \text{ K}$ and $J_{\parallel} = 1.0 \text{ K}$ used in fitting the experimental data of Ref. [59] may have some small deviation for fitting the experimental data of Ref. [64]. It is observed that the temperature induces a spin-flip in the gapped ground state.

5.4 $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$

5.4.1 Magnetic susceptibility. The ladder compound $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$, aka BPCB [47], has provided a new ground for understanding microscopic mechanisms in low-dimensional physics. The ladder structure extends along the a -axis [47]. The Cu^{2+} ions are bridged via the orbital overlap of Br^{-2} ions along the intra- and inter-chain directions. This compound was identified as a spin- $\frac{1}{2}$ Heisenberg two-leg ladder in the strong coupling regime with $J_{\perp} = 13.3 \text{ K}$ and $J_{\parallel} = 3.8 \text{ K}$ [47]. The gapped phase was observed directly from the experimental high field magnetization at low temperature with the typical rounded peak susceptibility shape at $T = 8 \text{ K}$. In fitting the HTE susceptibility to the experimental results, we find that the integrable ladder model (3) with coupling constants $J_{\perp} = 15.4 \text{ K}$, $J_{\parallel} = 1.2 \text{ K}$ and $g = 2.13$ describes this compound well. A comparison between the HTE result and experimental susceptibility is given in figure 19. A rounded peak is observed at $T \approx 8 \text{ K}$. The susceptibility exponentially decays as the temperature decreases, which indicates a gapped phase.

Figure 19. Susceptibility vs temperature comparison between the HTE method and the experimental data [47] for the compound $(C_5H_{12}N)_2CuBr_4$. The solid curve is the susceptibility evaluated directly from the HTE at $H = 0$ T. A parameter fit suggests the coupling constants $J_{\perp} = 15.4$ K and $J_{\parallel} = 1.2$ K with $g = 2.13$ and $\mu_B = 0.672$ K/T. The conversion constant is $\chi_{HTE} \approx 0.40615\chi_{EXP}$.

In this case the Troyer *et al* formula [66], $\chi \propto e^{-\Delta/T}/\sqrt{T}$, suggests a gap of $\Delta \approx 10$ K, which coincides with our TBA zero temperature gap $\Delta \approx 10.06$ K.

5.4.2 High field magnetization. The high field magnetization has been measured at different temperatures [47]. The experimental magnetization curve at $T = 0.7$ K reveals that the singlet gapped phase lies in the region $H < 6.6$ T and the saturation magnetization occurs at magnetic fields greater than $H_{c2} = 14.6$ T. The TBA magnetization curve is given in the inset of figure 20, where the parameter setting is the same as in figure 19. This curve indicates the critical field values $H_{c1} = 7$ T and $H_{c1} = 14.1$ T which are in agreement with the experimental result. It is seen that the HTE magnetization curves at $T = 1.75$ K (solid line) and $T = 3.31$ K (dashed line) in figure 20 fit the experimental curves well.

5.5 $[Cu_2(C_2O_2)(C_{10}H_8N_2)_2](NO_3)_2$

5.5.1 Magnetic susceptibility. The magnetic properties of the strong coupling ladder compound $[Cu_2(C_2O_2)(C_{10}H_8N_2)_2](NO_3)_2$ (abbreviated Cu-CON) were investigated experimentally in Ref. [161]. The spin-spin exchange interactions between Cu^{2+} ions along the leg and rung are bridged by NO_3^-

Figure 20. Magnetization vs magnetic field comparison between the HTE approach and the experimental data [47] for the compound $(C_5H_{12}N)_2CuBr_4$. These curves indicate the nature of the high magnetic field quantum phase diagram. The same parameters are used as in figure 19. The inset shows the exact TBA magnetization curve obtained at zero temperature.

and $C_2O_4^{2-}$, respectively and believed to be antiferromagnetic. The experimental susceptibility of $CuCON$ has a broad peak at about $T = 300$ K. Below this temperature, the susceptibility smoothly decreases, indicating a large gap. Perturbation theory predicts the gap $\Delta \approx J_{\perp} - J_{\parallel} \approx 360$ K. The HTE susceptibility evaluated from the free energy with the coupling constants $J_{\perp} = 520$ K, $J_{\parallel} = 10$ K, $g = 2.14$ and $\mu_B = 0.672$ K/T is shown in figure 21 (solid line). An overall good fit to the experimental curve is found. The inset of figure 21 shows the magnetization curves at different temperature. The TBA result predicts the critical field values $H_{c1} \approx 334$ T and $H_{c2} \approx 389$ T. These high field values appear to be experimentally inaccessible.

5.6 BIP-BNO

5.6.1 Magnetic susceptibility. The organic polyradical BIP-BNO has been recognised as a strong coupling ladder compound [159,160]. The intramolecular spin-spin exchange interaction within the BIP-BNO molecules is antiferromagnetic. Two intermolecular NO groups have the same crystallographic structure so that there is a twofold symmetry along the b -axis. It can be seen to give rise to an antiferromagnetic doubled rung interaction. Experimental investigation of the magnetic susceptibility reveals a broad peak at $T \approx 45$ K [159,160]. Below this temperature the susceptibility decreases steeply as the temperature decreases. Fitting the Troyer *et al* formula [66], $\chi \propto e^{-\Delta/T}/\sqrt{T}$, below $T = 25$ K gives [159,160] an energy gap $\Delta \approx 47$ K. To fit the susceptibility

Figure 21. Susceptibility vs temperature comparison between theory (solid line) and experimental data (circles) [161] for the ladder compound CuCON. The solid line is the susceptibility evaluated directly from the HTE at $H = 0$ T. A parameter fit suggests the coupling constants $J_{\perp} = 520$ K and $J_{\parallel} = 10$ K with $g = 2.14$ and $\mu_B = 0.672$ K/T. The inset shows the HTE magnetization versus magnetic field at different temperatures. The conversion constant is $\chi_{\text{HTE}} \approx 0.40615\chi_{\text{EXP}}$.

and the magnetization, two sets of coupling constants, $J_{\perp} = 73$ K, $J_{\parallel} = 17$ K and $J_{\perp} = 67$ K, $J_{\parallel} = 25$ K have been suggested [159,160]. However, the experimental magnetization curve at temperature $T = 1.6$ K indicates an energy gap $\Delta \approx 38.8$ T (roughly $\Delta \approx 52$ K). From perturbation theory, they calculated the gap $\Delta = J_{\perp} - J_{\parallel} = 56$ K or 42 K corresponding to the two sets of coupling parameters. There is obviously some inconsistency among these fittings. We find the parameters $J_{\perp} = 84$ K and $J_{\parallel} = 7.0$ K with $g = 2.0$ for the integrable ladder model (3) in fitting the susceptibility, as shown in figure 22. Here the value for the g -factor is fixed in the experiment [159,160]. The solid HTE line shows an excellent fit with experimental susceptibility curve. Here the TBA gives the gap $\Delta \approx 41$ T (roughly $\Delta \approx 55$ K), which is in agreement with the experimental observation of $\Delta \approx 38.8$ T. We conclude that their coupling constants $J_{\perp} = 73$ K and $J_{\parallel} = 17$ K seem to be more reasonable for the Heisenberg ladder. In addition, we mention that the conversion constant for this compound is twice as large as the one for the other compounds considered here, but of the same order as the one for the spin-1 chain compounds [154]. This is mainly because of the doubled intermolecular structure along the rungs, effectively forming two overlapping spin ladders.

Figure 22. Susceptibility vs temperature comparison between HTE theory and experiment [159,160] for the strong coupling ladder compound BIP-BNO. The solid line is the susceptibility evaluated directly from the HTE at $H = 0$ T. A parameter fit suggests the coupling constants $J_{\perp} = 83$ K and $J_{\parallel} = 7.0$ K with $g = 2.0$ and $\mu_B = 0.672$ K/T. The conversion constant is $\chi_{\text{HTE}} \approx 2 \times 0.40615 \chi_{\text{EXP}}$ due to the double chain structure.

6 Thermodynamics of the spin- $(\frac{1}{2}, 1)$ ladder model

In this section we turn to the calculation of the thermodynamic properties of the integrable mixed spin- $(\frac{1}{2}, 1)$ model (13). Various theoretical studies suggest that fractional magnetization plateaux exist in mixed spin- $(\frac{1}{2}, 1)$ chains [83,84,85,86,87,88,89,90] and the mixed spin ladders [82,81,80,190,191]. Such fractional magnetization plateaux have been found in a number of low-dimensional magnetic systems, including Shastry-Sutherland systems [76,74,75,192] and spin ladders [77,78,79,193,194,195].

6.1 TBA analysis and ground state properties

A one-third magnetization plateau has been found to exist in the integrable mixed spin- $(\frac{1}{2}, 1)$ ladder for strong rung coupling via the TBA approach [150]. Gapped or gapless states appear in turn as the external magnetic field increases, as can be seen in figure 23 where the whole magnetization curve is evaluated numerically by solving the TBA equations in the different phases [150]. This approach predicts that a two-component massless quantum magnetic phase lies in the regime $H < H_{c1}$, with a ferrimagnetic phase appearing for $H > H_{c1}$ where the component $\psi_{\frac{1}{2}}^{(-)}$ (recall (17)) becomes a physical ferrimagnetic ground state. This state forms a one third magnetization plateau which extends until the critical field value H_{c2} . As the magnetic field increases beyond H_{c2} , the state $\psi_{\frac{3}{2}}$ becomes involved in the ground state and the ground

state becomes a mixture of doublet and quadruplet states. The two components $\psi_{\frac{1}{2}}^{(-)}$ and $\psi_{\frac{3}{2}}$ form an effective XXZ model with massless excitations. Other components of the multiplets are gapful by virtue of both the rung coupling and magnetic field. Eventually, if the magnetic field is greater than H_{c3} , the ground state is the fully polarized state. The critical fields are found from the TBA to be [150]

$$\begin{aligned} H_{c1} &= \frac{4J_{\parallel}}{[g_s + \frac{1}{3}(g_s - g_t)]\mu_B} \\ H_{c2} &= \frac{3J_{\perp} - 8J_{\parallel}}{[(g_t + g_s) - \frac{1}{3}(g_s - g_t)]\mu_B} \\ H_{c3} &= \frac{3J_{\perp} + 8J_{\parallel}}{[(g_t + g_s) - \frac{1}{3}(g_s - g_t)]\mu_B}. \end{aligned} \quad (134)$$

The magnetization in the vicinity of the critical fields exhibits square root field dependent behaviour [150].

On the other hand, the first magnetization plateau depends mainly on the rung coupling. If $\frac{4}{3}J_{\parallel} \ln 2 < J_{\perp} < J_c^{+F}$, where

$$J_c^{+F} = \frac{8J_{\parallel}}{3} \frac{[\frac{1}{2}g_t + \frac{3}{2}g_s + \frac{1}{6}(g_s - g_t)]}{[g_s + \frac{1}{3}(g_s - g_t)]} \quad (135)$$

this plateau disappears and the critical points H_{c1} and H_{c2} become close to each other. Figure 24 shows the numerical evaluation of the full magnetization curve for weak rung coupling $J_{\perp} = 1.3$ K. We clearly see that the fractional magnetization plateau is closed. This is because the rung interaction can not quench the quadruplet. The numerical value is $H_{c1} \approx 0.605$ T. This implies that for $H < H_{c1}$ the ground state is the doublet spin liquid phase. The quadruplet component $\psi_{\frac{3}{2}}$ is involved in the groundstate for $H > H_{c1}$. Therefore the critical point H_{c1} indicates a quantum phase transition from a two-state phase to a three-state phase. Hence for $H > H_{c1}$, two Fermi seas, $\epsilon^{(1)}$ and $\epsilon^{(2)}$, are filled. However, the probability of the component $\psi_{\frac{3}{2}}$ quickly increases while the probability of the component $\psi_{-\frac{1}{2}}^{-}$ quickly decreases as the magnetic field increases. It follows that the magnetization increases rapidly in the region $H_{c1} < H < H_{c2}$, where the critical point H_{c2} indicates a phase transition from the three-state into the two-state phase. Thus from the theory we predict the critical field to be $H_{c2} = 6J_{\perp}/[(g_t + g_s) - \frac{1}{3}(g_s - g_t)]\mu_B - H_{c1} \approx 0.715$ T. This again is in agreement with the numerical value of $H_{c2} = 0.713$ T. In the region $H_{c2} < H < H_{c3}$ the two components $\psi_{\frac{1}{2}}^{-}$ and $\psi_{\frac{3}{2}}$ compete to be in the ground-

Figure 23. Magnetization versus magnetic field H for the integrable model (13) in the strong antiferromagnetic rung coupling regime. The magnetic moment is normalised by the saturation value $M_s = \frac{1}{2}(g_s + g_t)\mu_B$. The full curve is obtained from the TBA analysis. The coupling constants used are [150] $J_\perp = 6.0$ K, $J_\parallel = 0.4$ K with Landé g -factors $g_s = 2.22$, $g_t = 2.09$ and $\mu_B = 0.672$ K/T. We predict from the TBA analysis that the one-third saturation magnetization plateau opens with the critical fields $H_{c1} \approx 1.052$ T, $H_{c2} \approx 5.162$ T and $H_{c3} \approx 7.394$ T which coincide with the numerically estimated values. The dashed curve is evaluated from the HTE free energy (138). Both the TBA and HTE approaches are seen to yield consistent results. In addition, the inflection point at $H = H_{IP} \approx 6.278$ T and $M \approx 1$ is observed from the curves. H_{IP} indicates a point of equal probability for the states $\psi_{\frac{3}{2}}$ and $\psi_{\frac{1}{2}}^{(-)}$.

state. If the magnetic field is strong enough, so that $H > H_{c3}$ where H_{c3} is given in (134), the reference state $\psi_{\frac{3}{2}}$ becomes the true physical groundstate.

6.2 HTE approach

In order to investigate the thermodynamic properties, we again apply the HTE scheme which has been set up in section 4. Explicitly, the eigenvalue of the QTM (up to constants in the chemical potentials) is given by [131]

$$\begin{aligned}
 T_1^{(1)}(v) = & e^{-\beta\mu_1} \phi_-(v-i) \phi_+(v) \frac{Q_1(v + \frac{1}{2}i)}{Q_1(v - \frac{1}{2}i)} \\
 & + e^{-\beta\mu_2} \phi_-(v) \phi_+(v) \frac{Q_1(v - \frac{3}{2}i) Q_2(v)}{Q_1(v - \frac{1}{2}i) Q_2(v-i)}
 \end{aligned}$$

Figure 24. Magnetization versus magnetic field H in the weak antiferromagnetic rung coupling regime [150]. The numerical values are the same as for figure 23, but now using the smaller rung coupling constant $J_{\perp} = 1.3K < J_c^{+F} \approx 2.07K$. In this case the fractional magnetization plateau vanishes. The TBA critical fields coincide again with the numerically estimated values in the figure. The inset shows an enlargement of the magnetization between H_{c1} and H_{c2} .

$$\begin{aligned}
& +e^{-\beta\mu_3}\phi_{-}(v)\phi_{+}(v)\frac{Q_2(v-2i)Q_3(v-\frac{1}{2}i)}{Q_2(v-i)Q_3(v-\frac{3}{2}i)} \\
& +e^{-\beta\mu_4}\phi_{-}(v)\phi_{+}(v)\frac{Q_3(v-\frac{5}{2}i)Q_4(v-i)}{Q_3(v-\frac{3}{2}i)Q_4(v-2i)} \\
& +e^{-\beta\mu_5}\phi_{-}(v)\phi_{+}(v)\frac{Q_4(v-3i)Q_5(v-\frac{3}{2}i)}{Q_4(v-2i)Q_5(v-\frac{5}{2}i)} \\
& +e^{-\beta\mu_6}\phi_{-}(v)\phi_{+}(v+i)\frac{Q_5(v-\frac{7}{2}i)}{Q_5(v-\frac{5}{2}i)}. \tag{136}
\end{aligned}$$

In the above equations, the chemical potentials, μ_i , $i = 1, \dots, 6$, are chosen as

$$\begin{aligned}
\mu_1 &= -\left[\frac{3}{4}J_{\perp} + \frac{1}{2}g_s\mu_B h + \frac{1}{\sqrt{2}}J_{\perp}\sqrt{1 + \frac{1}{2}(g_s h' - g_t h' + \frac{1}{2})^2}\right] \\
\mu_2 &= -\left[\frac{3}{4}J_{\perp} - \frac{1}{2}g_s\mu_B h + \frac{1}{\sqrt{2}}J_{\perp}\sqrt{1 + \frac{1}{2}(g_s h' - g_t h' - \frac{1}{2})^2}\right]
\end{aligned}$$

$$\begin{aligned}
\mu_3 &= -(\tfrac{1}{2}g_t + g_s)\mu_B H \\
\mu_4 &= -\left[\tfrac{3}{4}J_\perp + \tfrac{1}{2}g_s\mu_B h - \tfrac{1}{\sqrt{2}}J_\perp\sqrt{1 + \tfrac{1}{2}(g_s h' - g_t h' + \tfrac{1}{2})^2}\right] \\
\mu_5 &= -\left[\tfrac{3}{4}J_\perp - \tfrac{1}{2}g_s\mu_B h - \tfrac{1}{\sqrt{2}}J_\perp\sqrt{1 + \tfrac{1}{2}(g_s h' - g_t h' - \tfrac{1}{2})^2}\right] \\
\mu_6 &= (\tfrac{1}{2}g_t + g_s)\mu_B H,
\end{aligned} \tag{137}$$

with $h' = \mu_B H/J_\perp$. These complicated chemical potentials make the HTE expansion of the free energy of the integrable model (13) more involved. As a matter of fact, for the applications we have in mind, the third-order term in the free energy is rather small. The higher order coefficients do not make a significant contribution to the free energy at high temperature. Therefore, for simplicity, we only consider the free energy up to third order, i.e.,

$$-\frac{1}{T}f(T, H) = \ln Q_1^{(1)} + c_{1,0}^{(1)}\left(\frac{J}{T}\right) + c_{2,0}^{(1)}\left(\frac{J}{T}\right)^2 + c_{3,0}^{(1)}\left(\frac{J}{T}\right)^3 + \dots \tag{138}$$

with the coefficients $c_{1,0}^{(1)}$, $c_{2,0}^{(1)}$ and $c_{3,0}^{(1)}$, along with the characters $\{Q_1^{(a)}\}$ for $su(6)$, given in Appendix B.

The exact free energy (138) allows easy access to the thermodynamic properties of the model (13) via the standard thermodynamic relations given in (129). Indeed, this approach makes it very easy to predict novel critical behaviour resulting from varying the strength of the rung and leg interactions. In figure 23, the magnetization curve (dashed line) at temperature $T = 0.6$ K, obtained from (138), indicates that the ground state remains in a gapless phase until the magnetic field exceeds the critical value $H_{c1} \approx 1.5$ T. The one-third magnetization plateau is also observed under the same parameter setting as that used for the TBA analysis. This magnetization plateau vanishes at the critical value $H_{c2} \approx 4.8$ T. An ordered ferrimagnetic phase is formed in the magnetization plateau region. As the field increases beyond the critical point 4.8 T, the magnetization increases almost linearly until the whole system is fully polarized at the critical value $H_{c2} \approx 7.8$ T. This phase diagram is consistent with the zero temperature TBA result, also shown in figure 23. This behaviour is reminiscent of the integrable spin- $\frac{3}{2}$ chain [154].

The susceptibility curve for this model is given in figure 25, with the same parameters as in figure 23. A gapless antiferromagnetic phase is observed from the susceptibility curve. However, the ordered antiferrimagnetic phase results in a cusp-like behaviour in the susceptibility. If the magnetization plateau is wider, the cusp-like effect becomes more obvious. The inset shows the susceptibility for the model with a weaker rung interaction, where the same pa-

Figure 25. Susceptibility vs temperature for the model (13) with the same parameters as in figure 23. The susceptibility curve indicates the antiferromagnetic behaviour in the absence of an energy gap. But in this case, the mid-plateau causes a cusp-like feature in the susceptibility curve at $T \approx 2.5$ K, similar to what is observed for the integrable spin- $\frac{3}{2}$ chain [154]. The inset shows the susceptibility curve with a weaker rung interaction $J_{\perp} = 1.3$ K, see figure 24. The mid-plateau is closed and no cusp-like behaviour is observed in the susceptibility curve.

parameter settings as figure 24 are used. As predicted from the TBA analysis, the magnetization plateau is closed. Thus the susceptibility shows standard antiferromagnetic behaviour without the cusp-like behaviour.

6.3 Organic ferrimagnetic mixed spin- $(\frac{1}{2}, 1)$ ladder

To the best of our knowledge, candidates for mixed spin- $(\frac{1}{2}, 1)$ compounds appear to be very rare due to their more complicated structure. Nevertheless, some organic ferrimagnets may have such mixed structures. One compound that we are aware of is the organic ferrimagnet PNNBNO [77, 78, 79], which has been recognised as a ladder compound with alternating spin- $\frac{1}{2}$ and spin-1 units, i.e., as two coupled alternating mixed spin chains. PNNBNO forms a ferrimagnetic ladder with antiferromagnetic rung and leg interaction. The structure along each leg consists of an alternating spin- $\frac{1}{2}$ and spin-1 chain, which is different from our theoretical model (13), which has uniform spin- $\frac{1}{2}$ on one leg and uniform spin-1 on the other. However, at high temperature, the thermodynamic properties are entirely dominated by the strong antiferromagnetic rung interaction. The integrable model (13) should therefore be expected to adequately describe the compound PNNBNO at high temperatures. In figure 26, we give the susceptibility curve evaluated from the exact HTE free energy (138). Figure 26 demonstrates that at high temperatures $T > 10$ K,

Figure 26. Susceptibility vs temperature for the mixed spin- $(\frac{1}{2}, 1)$ ladder PNNBNO. Circles represent the experimental data [77]. The solid line denotes the susceptibility $\chi \cdot T$ evaluated directly from the HTE free energy (138) with $J_{\perp} = 220$ K and $J_{\parallel} = 0.4$ K with $\mu_B = 0.672$ K/T and $g_s = g_t = 2.03$. The conversion constant is $\chi_{\text{HTE}} \approx 2 \times 0.40615 \chi_{\text{EXP}}$ due to the double-chain structure. The inset shows the magnetization curve predicted from HTE. A large mid-plateau forms a ferrimagnetic trimerization phase.

the theoretical HTE prediction fits the experimental results well. We see that the value χT derived from the HTE remains constant in the temperature range of 10 – 50 K, while it increases for temperatures over 50 K. This constant range reveals the mid-plateau effect – the ground state of the ladder lies in a ferrimagnetic state with $S^z = \frac{1}{2}$, see the inset of figure 26. When $T > 50$ K, the curves indicate antiferromagnetic behaviour. For low temperatures, the HTE χT values decrease as the temperature tends to zero. This indicates antiferromagnetic behaviour for the integrable mixed spin- $(\frac{1}{2}, 1)$ ladder. However, the experimental data for the susceptibility suggests ferromagnetic behaviour at low temperature due to the ferrimagnetic structure along the legs.

In addition, we predict the high temperature entropy at zero field in figure 27. It remains constant, i.e., at $S = 5.7569$ K/J-mol in the temperature range 10 – 50 K. The entropy increases as the quadruplet enters into the ground state from the ferrimagnetic phase (trimerization phase) for $T > 50$ K. In the ferrimagnetic phase, only the doublet component $S^z = \frac{1}{2}$ occupies the ground state. The theoretical prediction for the entropy in this phase is $NK_B \ln 2 \approx 5.76$ [77], which is in excellent agreement with our HTE value $S = 5.7569$ K/J-mol. Below $T \approx 10$ K the entropy decreases as the temperature tends to zero.

Figure 27. Entropy vs temperature for the the mixed spin- $(\frac{1}{2}, 1)$ ladder PNNBNO at high temperature. The curve evaluated from the HTE with the same constants as in figure 26 for zero field. In the temperature region 10 – 50 K, the entropy remains constant at the value $S = 5.7569$

K/J-mol, which is consistent with the theoretical value of $NK_b \ln 2 \approx 5.76$ K/J-mol [77]. It indicates a pure ferrimagnetic trimerization phase with total spin $S^z = \frac{1}{2}$. The conversion constant is $S_{\text{HTE}} \approx 2 \times 4.153 S_{\text{EXP}}$ (J/mol-Cu-K), due to the double-chain structure.

7 Magnetization plateaux for the spin-orbital model

In this section we discuss extending the analysis to the integrable spin-orbital model.

7.1 Hamiltonians

The transition metal oxides have been extensively studied in condensed matter physics due to their close connections to superconductivity. In particular, the electronic and spin properties of the D-electron shells of the transition metal ions lead to rich and novel phase transitions. In many metal oxide compounds [196, 197, 198, 199, 200], the orbital order has been observed besides charge and spin fluctuations. As a consequence, a great deal of interest [170, 201, 202, 203, 204, 171, 172, 205, 206, 157, 158] in spin-orbital models with both spin and orbit double degeneracies arises in this context. In the absence of Hund rule coupling, a simple spin-orbital model Hamiltonian is [171, 172]

$$\mathcal{H}_{\text{S-O}} = \sum_{j=1}^L \left(2\vec{S}_j \cdot \vec{S}_{j+1} + x \right) \left(2\vec{T}_j \cdot \vec{T}_{j+1} + y \right) \quad (139)$$

where x and y are arbitrary constants, $\vec{S}$ is a spin- $\frac{1}{2}$ operator and $\vec{T}$ is the orbital pseudospin- $\frac{1}{2}$ operator. The model has $su(2) \otimes su(2)$ symmetry.

The phase diagram of this model has been discussed in Refs. [171, 172, 205, 206, 207]. In the (x, y) -plane, there are five phases associated with different symmetries of the model. In phase I both spin and orbital degrees of freedom are in fully polarized ferromagnetic states. In phase II the orbital degrees of freedom are in the fully polarized ferromagnetic state while the spin degrees of freedom are in the antiferromagnetic ground state and vice versa in phase III. Phase IV is a gapped phase. Phase V is a gapless region surrounding the origin in the (x, y) -plane. The point $(\frac{1}{2}, \frac{1}{2})$ on the IV-V phase boundary has $su(4)$ symmetry. The simplest $su(4)$ spin-orbital model is given by the permutation operator. It has a rotation symmetry in the spin $\vec{S}$ and $\vec{T}$ spaces. In general, this symmetry is broken by Hund's rule coupling or other anisotropic hybridizations. In this section, we consider two types of symmetry breaking interactions: (1) spin-orbital Ising coupling [157, 158], and (2) orbital zero-field splitting [208], where the Hamiltonians are respectively given by

$$\mathcal{H}_{\text{S-O-I}} = \mathcal{H}_{\text{S-O-C}} + J_z \sum_{j=1}^L S_j^z T_j^z - \mu_B H \sum_{j=1}^L (g_s S^z + g_t T^z) \quad (140)$$

$$\mathcal{H}_{\text{S-O-S}} = \mathcal{H}_{\text{S-O-C}} + \Delta_z \sum_{j=1}^L T_j^z - \mu_B H \sum_{j=1}^L (g_s S^z + g_t T^z) \quad (141)$$

with

$$\mathcal{H}_{\text{S-O-C}} = J \sum_{j=1}^L \left(2\vec{S}_j \cdot \vec{S}_{j+1} + \frac{1}{2} \right) \left(2\vec{T}_j \cdot \vec{T}_{j+1} + \frac{1}{2} \right). \quad (142)$$

In the above equations, g_s and g_t denote Landé factors for spin and orbit. We see that for Model 1 (140) the $su(4)$ symmetry is broken into $su(2) \otimes su(2)$ due to the spin-orbital Ising coupling. For Model 2 (141) the $su(2)$ symmetry and rotation symmetry for the orbit are broken down by the presence of zero-field splitting caused by a crystalline field effect. We shall see that these different kinds of anisotropy can trigger different phase transitions in the presence of an external magnetic field.

7.2 Ground state properties and fractional magnetization plateaux

7.2.1 Model 1. In analogy to section 3, the model (140) can be diagonalised by the fundamental basis $|S^z, T^z\rangle$, with $|1\rangle = |\frac{1}{2}, \frac{1}{2}\rangle$, $|2\rangle = |\frac{1}{2}, -\frac{1}{2}\rangle$, $|3\rangle =$

$|\frac{1}{2}, \frac{1}{2}\rangle, |4\rangle = |-\frac{1}{2}, -\frac{1}{2}\rangle$, with energy [157, 158]

$$\begin{aligned} \mathcal{E} = & -J \sum_{i=1}^{M_1} \frac{1}{(v_i^{(1)})^2 + \frac{1}{4}} - \frac{1}{2} \mu_B H (g_s + g_t) N_1 \\ & - \frac{1}{2} [J_z + \mu_B H (g_s - g_t)] N_2 - \frac{1}{2} [J_z - \mu_B H (g_s - g_t)] N_3 \\ & + \frac{1}{2} \mu_B H (g_s + g_t) N_4 \end{aligned} \quad (143)$$

where N_i , $i = 1, 2, 3, 4$ are the occupation numbers of state $|i\rangle$ and the parameter $v_i^{(1)}$ satisfy the Bethe equations (11).

There is no spin singlet state as a result of the different spin and orbit Landé factors. The states $|2\rangle$ and $|3\rangle$ have nonzero magnetic moment. The Ising coupling J_z energetically favours the states $|2\rangle$ and $|3\rangle$. For very strong Ising coupling, these two states may form an effective $su(2)$ gapless phase. Following the TBA analysis given in section 3, for $J_z < 4J \ln 2$, we find that the states $|1\rangle$ and $|4\rangle$ are involved in the ground state in the absence of a magnetic field. In the presence of a magnetic field, the spin and orbit degrees of freedom undergo quite different magnetic ordering due to the Ising coupling. In the strong coupling regime $J_z \gg 4J \ln 2$, the states $|1\rangle$ and $|4\rangle$ are not involved in the ground state. When the magnetic field is applied, the spin and orbital degrees of freedom are both in an antiferromagnetic state but with opposite magnetic moment. Thus the ground state problem is reduced to solving the TBA equation

$$\epsilon^{(1)}(v) = -2\pi J a_1(v) + G_1 - \frac{1}{2\pi} \int_{-Q}^Q \frac{2\epsilon^{(1)-}(k)}{1 + (v - k)^2} dk \quad (144)$$

where the driving term $G_1 = (g_s - g_t)\mu_B H$ and Q denotes the Fermi boundary. The density $\rho^{(1)}(v)$ is determined by

$$\rho^{(1)}(v) = \frac{1}{2\pi} \frac{1}{v^2 + \frac{1}{4}} - \frac{1}{2\pi} \int_{-Q}^Q \frac{2\rho^{(1)}(k)}{1 + (v - k)^2} dk. \quad (145)$$

If $g_s > g_t$, due to Zeeman splitting, the energy level of state $|3\rangle$ becomes higher while state $|2\rangle$ becomes lower as the magnetic field increases. As a consequence, the magnetization for the spin degrees increases whereas the orbital magnetization decreases. If the magnetic field is strong, i.e., $H > H_{c1}$,

Figure 28. Magnetization versus magnetic field H in units of saturation magnetization $M_s = \frac{1}{2}(g_s + g_t)\mu_B$ for the spin orbital model (140). This figure illustrates the magnetization plateau obtained from the model via the TBA with $J_z = 18$ K and $J = 0.4$ K with $g_s = 2$ and $g_t = 1$. The inset shows the magnetization for the spin and orbital degrees of freedom.

with the critical value

$$H_{c1} = \frac{4J}{\mu_B(g_s - g_t)} \quad (146)$$

all sites are occupied by state $|2\rangle$, with no state $|3\rangle$ appearing in the ground state. Thus a magnetization plateau with magnetic moment $M = \frac{1}{2}\mu_B(g_s - g_t)$ opens up. The spin and orbital degrees of freedom become fully polarized, but the orbital moment direction is antiparallel to the magnetic field. Explicitly, the total magnetization is $M = \mu_B g_s S^z + \mu_B g_t T^z$, with the spin and orbit magnetizations given by

$$S^z = \frac{1}{2} - \int_{-Q}^Q \rho^{(1)}(v) dv, \quad T^z = -\frac{1}{2} + \int_{-Q}^Q \rho^{(1)}(v) dv. \quad (147)$$

The spin and orbit magnetization and the total magnetization may be obtained by numerically solving (144) and (145). The results as presented in figure 28.

On the other hand, the magnetic field can induce the state $|1\rangle$ into the ground state. The magnetic plateau vanishes at the critical point

$$H_{c2} = \frac{J_z - 8J}{2\mu_B g_t} \quad (148)$$

where the phase transition from a ferrimagnetic phase (with both spin and orbital degrees of freedom fully polarized) into an antiferromagnetic phase occurs. In this antiferromagnetic phase the spin degrees are fully-polarized while the orbital degrees of freedom are in an antiferromagnetic state. We notice that in the regime $H_{c2} \leq H < \frac{J_z}{2\mu_B g_t}$ the driving term in (144) is $G_1 = \frac{1}{2}J_z - \mu_B g_t H$. Correspondingly, the magnetization for the spin and orbital degrees of freedom is given by $S^z = \frac{1}{2}$ and $T^z = -\frac{1}{2} + \int_{-Q}^Q \rho^{(1)}(v)dv$. In the regime $\frac{J_z}{2\mu_B g_t} \leq H < H_{c3}$, the driving term is $G_1 = -\frac{1}{2}J_z + \mu_B g_t H$, thus the magnetization is changed to $T^z = \frac{1}{2} - \int_{-Q}^Q \rho^{(1)}(v)dv$ for the orbital degrees of freedom. As the magnetic field increases, the state $|1\rangle$ occupies more and more sites in the ground state. For strong magnetic fields, i.e., $H > H_{c3}$, both the spin and orbital degrees of freedom are fully polarized. The critical field H_{c3} is given by

$$H_{c3} = \frac{J_z + 8J}{2\mu_B g_t}. \quad (149)$$

The critical behaviour in the vicinity of the critical points is a Pokrovsky-Talapov-type transition as indicated in figure 28.

7.2.2 Model 2. In the above fundamental basis, the nested algebraic Bethe Ansatz gives the energy for model 2 in the form

$$\begin{aligned} \mathcal{E} = & -J \sum_{i=1}^{M_1} \frac{1}{(v_i^{(1)})^2 + \frac{1}{4}} - \frac{1}{2} \mu_B H (g_s + g_t) N_1 \\ & - [\Delta_z + \frac{1}{2} \mu_B H (g_s - g_t)] N_2 + \mu_B H (g_s - g_t) N_3 \\ & - [\Delta_z - \frac{1}{2} \mu_B H (g_s - g_t)] N_4. \end{aligned} \quad (150)$$

Here N_i , $i = 1, 2, 3, 4$ are the occupation numbers of state $|i\rangle$ and the parameters $v_i^{(1)}$ satisfy the Bethe equations (11).

The orbit splitting Δ_z energetically favours the states $|2\rangle$ and $|4\rangle$. For a very large orbital splitting, these two states may form an effective $su(2)$ gapless phase. Performing the TBA analysis we find that for $\Delta_z > 2J \ln 2$ the states $|1\rangle$ and $|3\rangle$ are gapful in the absence of a magnetic field. Therefore, in this case the ground state problem is reduced to the $su(2)$ TBA equation (144) with the driving term $G_1 = g_s \mu_B H$. The density $\rho^{(1)}(v)$ is determined by (145). In this mixed state, the orbital degrees of freedom can be in a fully polarized state,

Figure 29. Magnetization versus magnetic field H in units of saturation magnetization $M_s = \frac{1}{2}(g_s + g_t)\mu_B$ for the spin orbital model (141). This figure exhibits the magnetization plateau obtained through the TBA with $\Delta_z = 8$ K and $J = 0.4$ K with $g_s = 2$ and $g_t = 1$. The inset shows the magnetization for the spin and orbital degrees of freedom.

while the spin degrees are in an antiferromagnetic phase. Again we assume $g_s > g_t$, then the energy level of state $|4\rangle$ becomes higher and the energy level of state $|2\rangle$ becomes lower as the magnetic field increases. As a consequence, the magnetization of the spin degrees increases. If the magnetic field is larger than the critical value H_{c1} , given by

$$H_{c1} = \frac{4J}{\mu_B g_s} \quad (151)$$

the state $|2\rangle$ occupies all sites, while the state $|4\rangle$ is not involved in the ground state. Here a magnetization plateau with magnetic moment $M = \frac{1}{2}\mu_B(g_s - g_t)$ opens. The spin and orbital degrees of freedom are both fully polarized, as seen in the inset of figure 29. Explicitly, in the region $H < H_{c1}$, the total magnetization is $M = \mu_B g_s S^z + \mu_B g_t T^z$, with the spin and orbit magnetizations given by

$$S^z = \frac{1}{2} - \int_{-Q}^Q \rho^{(1)}(v) dv, \quad T^z = -\frac{1}{2}. \quad (152)$$

The values of the spin and orbit magnetization and the total magnetization may be again obtained by numerically solving (144) and (145), the results of which are shown in figure 29.

For this model the magnetic plateau vanishes for magnetic fields greater

than H_{c2} , due to the involvement of state $|1\rangle$. This critical field has the value

$$H_{c2} = \frac{\Delta_z - 4J}{\mu_B g_t}. \quad (153)$$

At the further critical point H_{c2} a phase transition from a ferrimagnetic phase into an antiferromagnetic phase occurs. In this phase, the spin state is fully polarized, whereas the orbit is in an antiferromagnetic state. As the magnetic field increases, state $|2\rangle$ becomes less involved in the ground state. For a strong magnetic field, i.e., $H > H_{c3}$, both the spin and orbit degrees are fully polarized. Thus the state $|1\rangle$ becomes the true physical ground state. The critical point H_{c3} is given by

$$H_{c2} = \frac{\Delta_z + 4J}{\mu_B g_t}. \quad (154)$$

These phase transition points for model 2 (141) are clearly indicated in figure 29.

We conclude this section by remarking that the thermodynamic properties of the spin orbital models are easily accessible from the HTE, along the lines discussed earlier in section 4. As yet there appears to be a lack of relevant real materials, so we do not discuss this further.

8 Concluding remarks

In this article we have reviewed a systematic approach for investigating the thermal and magnetic properties of the integrable two-leg spin ladder models. The thermodynamic Bethe Ansatz (TBA) and High Temperature Expansion (HTE) methods used to analyse the ground state properties at zero temperature and the thermodynamics at finite temperatures have been described in detail. The TBA approach outlined in section 3 is best suited to the calculation of physical properties at zero temperature. On the other hand, the HTE method outlined in section 4 provides an exact expansion for the free energy. Although the HTE method involves sophisticated mathematical calculations, the resulting expansion for the free energy, e.g., equations (128) and (138), is relatively simple. In practice it suffices to consider only the first few terms in the expansion and the relevant thermal and magnetic properties follow almost trivially as derivatives to the free energy. In this way the integrable spin- $\frac{1}{2}$ ladder model defined in section 2.1 can be used to examine the physics of a number of strong coupling ladder compounds which have been extensively studied in the literature. The two-leg ladder compounds discussed in section 5

are $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$ [42], $\text{Cu}_2(\text{C}_5\text{H}_{12}\text{N}_2)_2\text{Cl}_4$ [43,44,45], $(\text{C}_5\text{H}_{12}\text{N})_2\text{CuBr}_4$ [47], BIP-BNO [159,160] and $[\text{Cu}_2(\text{C}_2\text{O}_2)(\text{C}_{10}\text{H}_8\text{N}_2)_2](\text{NO}_3)_2$ [161]. The critical magnetic fields derived from the TBA equations are in good agreement with the experimental results for the compounds considered. The exact results obtained for the susceptibility, the specific heat, the magnetization and the entropy obtained from the HTE method provide excellent overall agreement with the known experimental data.

In addition to these results, the ground state and thermodynamic properties of the integrable mixed spin- $(\frac{1}{2}, 1)$ ladder model defined in section 2.2 have been investigated via the TBA and HTE in section 6. The results have been used to examine the magnetic properties of the ferrimagnetic mixed spin ladder compound PNNBNO [77, 78, 79]. Two integrable spin orbital models based on an underlying $su(4)$ symmetry were discussed in section 7. It was seen that both the single-ion anisotropy and the zero-field orbital splitting can trigger a fractional magnetization plateau with respect to different Landé factors for the spin and orbital degrees of freedom. The phase diagrams for the two spin orbital models were also discussed.

It is evident from these results that integrable models can provide an alternative way to investigate the thermal and magnetic properties of a number of low-dimensional ladder compounds. For arbitrary two-leg spin- (s, S) ladders with strong rung coupling, where spins of value s and S reside on different legs, the rung interaction terms $J_\perp \sum_{j=1}^L \vec{S}_j \cdot \vec{s}_j$ and $\tilde{J}_\perp \sum_{j=1}^L (\vec{S}_j \cdot \vec{s}_j)^2$ may overwhelm the spin-spin intrachain interactions and dominate the low temperature behaviour. Therefore it is not surprising that the physics of the spin- (s, S) ladder compounds may be captured by the integrable spin- (s, S) ladder models based on $su(n)$ symmetry, where $n = (2s + 1)(2S + 1)$. For instance, the integrable spin-1 ladder with sophisticated rung interaction may trigger three gapped phases with magnetization plateaux at $M/M_s = 0, \frac{1}{2}, 1$, which are also found to exist in spin chains [209, 210, 211]. However, the spin-1 ladder compound BIP-TENO [212, 213, 214, 215] exhibits a magnetization plateau at $\frac{1}{4}$ which is induced by frustration in the next neighbour interactions along the legs. Obviously, the integrable spin-1 ladder model does not favor the $\frac{1}{4}$ magnetization plateau. Nevertheless, it may be used to analyse the fractional magnetization plateau for a known spin-1 alternating chain compound [194]. In fact, there are relatively few of the more exotic spin ladder compounds. The predictive power of this approach has yet to be fully exploited.

Finally, we emphasize that the gapped phase induced by strong rung interaction in the spin ladder models is the field-induced singlet ground state which is similar to the phase induced by a large single-ion anisotropy for the integrable spin chains [153, 154]. The transition is of the universal Pokrovsky-Talapov type. The universal nature of the critical fields is seen in the full $H - T$ phase diagram. For example, the phase diagram for the compounds

Figure 30. Phase diagrams for the compounds B5i2aT and Cu(Hp)Cl with spin couplings used in sections 5.2 and 5.3. Similar phase diagrams are found using the HTE approach for the other spin ladder compounds discussed in section 5. In general the critical point H_{c2} approaches the critical point H_{c1} as $J_{||}$ decreases. For $J_{||} = 0$ the two critical points merge at zero temperature.

B5i2aT and Cu(Hp)Cl is shown in Fig. 30. It is anticipated that this phase diagram may be further extended into the low temperature region using the recently derived nonlinear integral equations for the thermodynamics of the $su(4)$ model [216]. In general thermal fluctuations increase the saturation field and diminish the energy gap. The slopes of the critical curves indicate that the estimated values of H_{c1} and H_{c2} at $T = 0$ K coincide with the TBA results given in table 1. The field-induced gapped phase is significantly different from the Haldane valence bond solid state or the dimerization in the spin-Peierls transition. The former does not exhibit long range order spin-spin correlations, however the latter may.

The HTE scheme also provides a means of calculating correlation functions for integrable models. In particular, there are multiple integral formulae [217] (see also, Refs. [218, 219, 220, 221, 222]) for the density matrix of the one-dimensional Heisenberg model in a magnetic field for any finite temperature. The evaluation of the multiple integral formulae is of interest because any correlation functions for the model can be written in terms of the density matrix. The HTE method has been applied [223, 224] for their formulae for short ranged case and proved to be useful to evaluate them. In the case of zero magnetic field, there is a different way [225, 226] to calculate the HTE of correlation functions. It will be worthwhile to explore correlation functions of

the integrable ladder models.

A particularly exciting development for quantum science in general is that fundamental interacting spin systems, traditionally realised in the context of condensed-matter based systems like those discussed in this article, may also be realised by trapping atoms in optical lattices. This atom-optics based setting [227] offers a potentially cleaner environment to mimic and study condensed matter physics phenomena. It offers, for example, a way to construct a complete toolbox for realising various kinds of spin models [228,229]. It also provides a way of realising low-dimensional quantum systems, for which the spatial confinement leads to enhanced dynamics and correlations. Integrable models, and the methods reviewed in this article for calculating their physical properties, will clearly continue to have a bearing on these developments. This is because they treat genuine interacting quantum many-body systems for which perturbative approaches and mean-field theories often fail. The methods discussed here may be generalised to spin systems with open boundary conditions or impurities [230]. This is particularly important for small-sized systems in which quantum fluctuations may be strong enough that boundary effects are no longer negligible at low temperature. In general obtaining an exact systematic low-temperature expansion for integrable models in analogy with the HTE remains an outstanding open problem. So too does the development of exact expansion methods for the integrable Bose and Fermi gases.

Appendix A: $su(4)$ HTE coefficients

The first five coefficients in the HTE for the free energy (128) of the integrable spin ladder (3) are explicitly given by

$$\begin{aligned}
c_{1,0}^{(1)} &= \frac{2Q_1^{(2)}}{Q_1^{(1)2}} \\
c_{2,0}^{(1)} &= \frac{3Q_1^{(2)}}{Q_1^{(1)2}} - \frac{6Q_1^{(2)2}}{Q_1^{(1)4}} + \frac{3Q_1^{(3)}}{Q_1^{(1)3}} \\
c_{3,0}^{(1)} &= \frac{10Q_1^{(2)}}{3Q_1^{(1)2}} - \frac{18Q_1^{(2)2}}{Q_1^{(1)4}} + \frac{80Q_1^{(2)3}}{3Q_1^{(1)6}} + \frac{8Q_1^{(3)}}{Q_1^{(1)3}} - \frac{24Q_1^{(2)}Q_1^{(3)}}{Q_1^{(1)5}} + \frac{4Q_1^{(4)}}{Q_1^{(1)4}} \\
c_{4,0}^{(1)} &= \frac{35Q_1^{(2)}}{12Q_1^{(1)2}} - \frac{205Q_1^{(2)2}}{6Q_1^{(1)4}} + \frac{120Q_1^{(2)3}}{Q_1^{(1)6}} - \frac{140Q_1^{(2)4}}{Q_1^{(1)8}} + \frac{55Q_1^{(3)}}{4Q_1^{(1)3}} - \frac{100Q_1^{(2)}Q_1^{(3)}}{Q_1^{(1)5}} \\
&\quad + \frac{180Q_1^{(2)2}Q_1^{(3)}}{Q_1^{(1)7}} - \frac{45Q_1^{(3)2}}{2Q_1^{(1)6}} + \frac{15Q_1^{(4)}}{Q_1^{(1)4}} - \frac{40Q_1^{(2)}Q_1^{(4)}}{Q_1^{(1)6}} \\
c_{5,0}^{(1)} &= \frac{21Q_1^{(2)}}{10Q_1^{(1)2}} - \frac{50Q_1^{(2)2}}{Q_1^{(1)4}} + \frac{320Q_1^{(2)3}}{Q_1^{(1)6}} - \frac{840Q_1^{(2)4}}{Q_1^{(1)8}} + \frac{4032Q_1^{(2)5}}{5Q_1^{(1)10}} + \frac{37Q_1^{(3)}}{2Q_1^{(1)3}} \\
&\quad - \frac{249Q_1^{(2)}Q_1^{(3)}}{Q_1^{(1)5}} + \frac{1020Q_1^{(2)2}Q_1^{(3)}}{Q_1^{(1)7}} - \frac{1344Q_1^{(2)3}Q_1^{(3)}}{Q_1^{(1)9}} - \frac{120Q_1^{(3)2}}{Q_1^{(1)6}} \\
&\quad + \frac{378Q_1^{(2)}Q_1^{(3)2}}{Q_1^{(1)8}} + \frac{34Q_1^{(4)}}{Q_1^{(1)4}} - \frac{210Q_1^{(2)}Q_1^{(4)}}{Q_1^{(1)6}} + \frac{336Q_1^{(2)2}Q_1^{(4)}}{Q_1^{(1)8}} - \frac{72Q_1^{(3)}Q_1^{(4)}}{Q_1^{(1)7}}.
\end{aligned}$$

The Q functions are defined in (115).

Appendix B: $su(6)$ HTE coefficients

The first three coefficients in the HTE for the free energy (138) of the integrable mixed spin ladder (13) are explicitly given by

$$\begin{aligned}
c_{1,0}^{(1)} &= 2 \frac{Q_1^{(2)}}{Q_1^{(1)2}} \\
c_{2,0}^{(1)} &= 3 \frac{Q_1^{(2)}}{Q_1^{(1)2}} - 6 \frac{Q_1^{(2)2}}{Q_1^{(1)4}} + 3 \frac{Q_1^{(3)}}{Q_1^{(1)3}} \\
c_{3,0}^{(1)} &= \frac{10}{3} \frac{Q_1^{(2)}}{Q_1^{(1)2}} - 18 \frac{Q_1^{(2)2}}{Q_1^{(1)4}} + \frac{80}{3} \frac{Q_1^{(2)3}}{Q_1^{(1)6}} + 8 \frac{Q_1^{(3)}}{Q_1^{(1)3}} - 24 \frac{Q_1^{(2)} Q_1^{(3)}}{Q_1^{(1)5}} + 4 \frac{Q_1^{(4)}}{Q_1^{(1)4}}.
\end{aligned}$$

In turn the characters of the antisymmetric representations of $su(6)$ are explicitly written in terms of the chemical potentials (137) as

$$\begin{aligned}
Q_1^{(1)} &= e^{-\beta\mu_1} + e^{-\beta\mu_2} + e^{-\beta\mu_3} + e^{-\beta\mu_4} + e^{-\beta\mu_5} + e^{-\beta\mu_6} \\
Q_1^{(2)} &= e^{-\beta(\mu_1+\mu_2)} + e^{-\beta(\mu_1+\mu_3)} + e^{-\beta(\mu_1+\mu_4)} + e^{-\beta(\mu_1+\mu_5)} + e^{-\beta(\mu_1+\mu_6)} \\
&\quad + e^{-\beta(\mu_2+\mu_3)} + e^{-\beta(\mu_2+\mu_4)} + e^{-\beta(\mu_2+\mu_5)} + e^{-\beta(\mu_2+\mu_6)} + e^{-\beta(\mu_3+\mu_4)} \\
&\quad + e^{-\beta(\mu_3+\mu_5)} + e^{-\beta(\mu_3+\mu_6)} + e^{-\beta(\mu_4+\mu_5)} + e^{-\beta(\mu_4+\mu_6)} + e^{-\beta(\mu_5+\mu_6)} \\
Q_1^{(3)} &= e^{-\beta(\mu_1+\mu_2+\mu_3)} + e^{-\beta(\mu_1+\mu_2+\mu_4)} + e^{-\beta(\mu_1+\mu_2+\mu_5)} + e^{-\beta(\mu_1+\mu_2+\mu_6)} \\
&\quad + e^{-\beta(\mu_2+\mu_3+\mu_4)} + e^{-\beta(\mu_2+\mu_3+\mu_5)} + e^{-\beta(\mu_2+\mu_3+\mu_6)} + e^{-\beta(\mu_2+\mu_4+\mu_5)} \\
&\quad + e^{-\beta(\mu_2+\mu_4+\mu_6)} + e^{-\beta(\mu_2+\mu_5+\mu_6)} + e^{-\beta(\mu_3+\mu_4+\mu_5)} + e^{-\beta(\mu_3+\mu_4+\mu_6)} \\
&\quad + e^{-\beta(\mu_3+\mu_5+\mu_6)} + e^{-\beta(\mu_4+\mu_5+\mu_6)} \\
Q_1^{(4)} &= e^{-\beta(\mu_1+\mu_2+\mu_3+\mu_4)} + e^{-\beta(\mu_1+\mu_2+\mu_3+\mu_5)} + e^{-\beta(\mu_1+\mu_2+\mu_3+\mu_6)} \\
&\quad + e^{-\beta(\mu_1+\mu_2+\mu_4+\mu_5)} + e^{-\beta(\mu_1+\mu_2+\mu_4+\mu_6)} + e^{-\beta(\mu_1+\mu_2+\mu_5+\mu_6)} \\
&\quad + e^{-\beta(\mu_1+\mu_3+\mu_4+\mu_5)} + e^{-\beta(\mu_1+\mu_3+\mu_4+\mu_6)} + e^{-\beta(\mu_1+\mu_3+\mu_5+\mu_6)} \\
&\quad + e^{-\beta(\mu_1+\mu_4+\mu_5+\mu_6)} + e^{-\beta(\mu_2+\mu_3+\mu_4+\mu_5)} + e^{-\beta(\mu_2+\mu_3+\mu_4+\mu_6)} \\
&\quad + e^{-\beta(\mu_2+\mu_3+\mu_5+\mu_6)} + e^{-\beta(\mu_2+\mu_4+\mu_5+\mu_6)} + e^{-\beta(\mu_3+\mu_4+\mu_5+\mu_6)} \\
Q_1^{(5)} &= e^{-\beta(\mu_1+\mu_2+\mu_3+\mu_4+\mu_5)} + e^{-\beta(\mu_1+\mu_2+\mu_3+\mu_4+\mu_6)} + e^{-\beta(\mu_2+\mu_3+\mu_4+\mu_5+\mu_6)} \\
Q_1^{(6)} &= e^{-\beta(\mu_1+\mu_2+\mu_3+\mu_4+\mu_5+\mu_6)} = e^{3J_\perp/T}.
\end{aligned}$$

Appendix C: Location of Bethe roots and zeros of the largest QTM eigenvalue

In this Appendix the location of Bethe roots and zeros of the largest QTM eigenvalue are illustrated for finite systems.

Figure C1. (left) Location of roots $v_k^{(a)}$ ($a = 1, 2, 3$) of the $su(4)$ Bethe equations (103) in the complex plane. The parameters are $N = 12$, $M_1 = M_2 = M_3 = N/2 = 6$ and $u_N = -0.05$, with no chemical potentials ($\mu_i = 0$ for $i = 1, 2, 3, 4$). Symbols $\circ$, $\square$, $\triangle$ denote colours 1, 2, 3, respectively.

Note that the roots of each colour form 6 one-strings. (right) Location of the zeros of the corresponding largest QTM eigenvalue $\tilde{T}_1^{(a)}(v)$ ($a = 1, 2, 3$) in the complex plane. The symbols $\circ$, $\square$, $\triangle$ denote colours 1, 2, 3, respectively. Note the ‘physical strip’ around the real axis which is free of zeros.

Figure C2. (top left) Location of roots $v_k^{(a)}$ ($a = 1, 2, 3$) of the $su(4)$ Bethe equations (103) in the complex plane corresponding to the largest eigenvalue of the QTM for magnetic fields $H = 5$ T, 9 T and 13 T. Symbols $\diamond$, $+$, $\times$ denote the roots of colour 1, 2, 3, respectively. The parameters are $N = 12$ and $T = 1.59$ K, with chemical potentials given by equation (86), i.e., $\mu_1 = -13.3$ K, $\mu_2 = -1.4112 H$, $\mu_3 = 0$ and $\mu_4 = -\mu_2$. These values correspond to the compound $(5\text{IAP})_2\text{CuBr}_4 \cdot 2\text{H}_2\text{O}$ (see figure 4) with $J_\perp = 13.3$ K. The remaining figures are more detailed versions of this figure. (top right) Location of the Bethe roots $v_k^{(1)}$. Symbols $\circ$, $\square$, $\triangle$ denote magnetic fields of $H = 5$ T, 9 T and 13 T, respectively. (bottom left) Location of the Bethe roots $v_k^{(2)}$. (bottom right) Location of the Bethe roots $v_k^{(3)}$.

Figure C3. (top left) Location of the zeros of the largest QTM eigenvalue $\tilde{T}_1^{(a)}(v)$ ($a = 1, 2, 3$) in the complex plane corresponding to the Bethe roots in figure C2 for the same numerical parameters. This figure is an overlay of the other three figures and corresponds to the top left of figure C2. Symbols $\diamond$, $+$, $\times$ denote the zeros for colours 1, 2, 3, respectively. Note that the ‘physical strip’ around the real axis is free of zeros for each of the magnetic fields, in accord with Conjecture 4.1 The remaining panels show the location of zeros of $\tilde{T}_1^{(a)}(v)$ for the corresponding Bethe root distributions in figure C2. Symbols $\circ$, $\square$, $\triangle$ denote magnetic fields $H = 5$ T, 9 T and 13 T, respectively. (top right) Colour $a = 1$. (bottom left) Colour $a = 2$. (bottom right) Colour $a = 3$.
